1.12.2.1.1. Sensory transduction and the periphery Olfaction is a chemical sense. Olfactory receptor neurons (ORNs) respond to a particular subset of all possible odorant compounds. This receptive range can be very large in some cases and extremely specific in others. Detection depends on the stereochemical binding of an odorant molecule to an olfactory receptor (OR) protein present in the plasma membrane of ORN dendrites. Large families of putative olfactory receptors were initially identified in mammals (Buck and Axel, 1991). Among insects, ORs were first identified in *Drosophila* (Clyne *et al.*, 1999b; Gao and Chess, 1999; Vosshall *et al.*, 1999); the present size of this gene family, named *Drosophila* olfactory receptors (DORs), stands at 61, although expression cannot be detected for a large fraction of these. The published genome sequence of the mosquito *Anopheles gambiae* has permitted the identification of a family of ~79 receptors (Hill *et al.*, 2002), while a number of ORs from the moth, *Heliothis virescens,* have also been cloned (Krieger *et al.*, 2002). In addition to these families of presumed odorant receptors, a second family of presumed gustatory receptors (GRs) has been identified in *Drosophila* (Clyne *et al.*, 2000; Scott *et al.*, 2001b), and more recently *Anopheles* (Hill *et al.*, 2002). Scott *et al.* (2001b) were able to identify 56 putative GRs in the *Drosophila* genome; interestingly, three of seven GRs whose expression could be detected by *in situ* hybridization were expressed in the antenna, rather than gustatory structures. Indeed, the axons of ORNs expressing the *GR21a* gene seem to send axons to glomerulus V of the antennal lobe (Scott *et al.*, 2001b). All of these receptors (ORs and GRs) are seven transmembrane proteins, which are believed to couple to G protein-linked cascades. These G protein-linked cascades eventually cause membrane depolarization and the firing of action potentials, which travel down the ORN axon into the central nervous system (CNS).

Since olfactory receptors determine the receptive range of ORNs, what is the logic of their expression?

In mice, individual ORNs appear to express a single OR; indeed OR expression appears to be under strict control, so that any particular ORN does not even coexpress both alleles of the same OR gene (Chess *et al.*, 1994). In *Drosophila*, ORNs also seem to express only one specific DOR (Vosshall *et al.*, 2000), although control of gene expression seems to be less strict, since an example of coexpression of two OR genes at adjacent chromosomal locations has already been reported (Dobritsa *et al.*, 2003). As would be expected if a single receptor type confers the receptive range on any particular neuron, deletion of a single receptor gene can lead to the loss of olfactory responsivity in neurons that would normally express it. Conversely, ectopic expression of another OR in this mutant background could confer the receptive range of another ORN class on this cell (Dobritsa *et al.*, 2003).

In addition to those DORs that show selective expression, one divergent member of the DOR family, OR83b, is expressed in a large fraction, perhaps 80%, of all ORNs (Vosshall *et al.*, 2000). The functional significance of this observation is still unclear, although a coreceptor function remains a possibility. Interestingly, while it has not been possible to identify orthologs of the main group of DORs in other insects, OR83b is highly conserved and has been identified in eight insect species including examples of Diptera, Lepidoptera, Hymenoptera, and Coeloptera (Krieger *et al.*, 2003).

1.12.2.1.2. Central representations and processing In *Drosophila* and mice, olfactory receptor neuron axons bearing the same olfactory receptor terminate in discrete foci (glomeruli), in the first olfactory relay of the brain, the antennal lobe (AL) or olfactory bulb, respectively (*Drosophila*: Gao *et al.*, 2000; Vosshall *et al.*, 2000; mice: Ressler *et al.*, 1994; Vassar *et al.*, 1994; Mombaerts *et al.*, 1996; Wang *et al.*, 1998). The anatomical details of this arrangement are schematized in **Figure 1** and discussed in detail below (Section 1.12.2.2.2). The functional implication of this convergence, in conjunction with the broad tuning of ORs mentioned above, is that olfactory coding appears to be, at least in part, combinatorial; particular odorants activate discrete and reproducible sets of glomeruli (e.g., *Apis*: Galizia *et al.*, 1999b; *Drosophila*: Rodrigues, 1988; Fiala *et al.*, 2002; Ng *et al.*, 2002b; Wang *et al.*, 2003; *Heliothis*: Galizia *et al.*, 2000; vertebrates: Friedrich and Korsching, 1997; Rubin and Katz, 1999).

Olfactory processing within the antennal lobe remains a topic of great interest and some controversy. A substantial body of work in locusts has emphasized the significance of antennal lobe processing, especially via inhibitory interactions between glomeruli, which may generate temporally patterned responses. This temporal patterning includes fast oscillatory behavior, which has been widely observed in vertebrate and invertebrate olfactory systems, as well as slower temporal modulation of the firing rate in a spike train resulting from a particular odorant presentation (reviews: Laurent, 1997; Laurent *et al.*, 2001). In contrast, recent studies in *Drosophila*, using optical imaging of genetically encoded sensors of neuronal activity, have concluded that the information entering the lobe (via ORNs) and leaving the lobe (via projection neurons, PNs; **Figure 1**) shows relatively little sign of processing (Ng *et al.*, 2002b; Wang *et al.*, 2003). The distinction may reflect the much greater

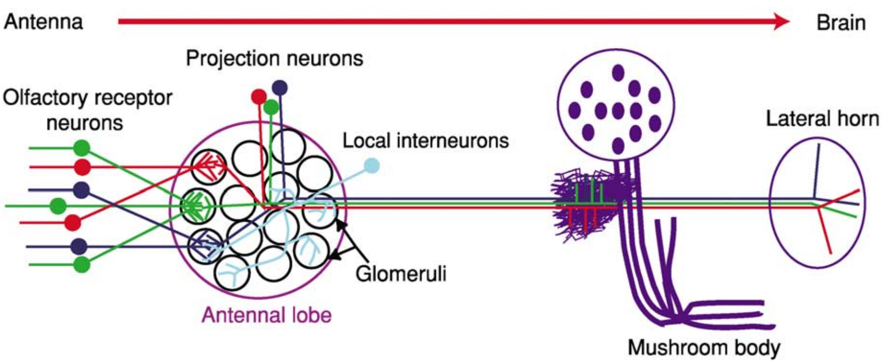

Figure 1 Schematic of olfactory system organization. Cartoon depicting the logical arrangement of components of the insect olfactory system. Olfactory receptor neurons (ORNs) project their axons to individual glomeruli according to the olfactory receptor (OR) they express. Projection Neurons (PNs) send dendrites to individual glomeruli and their axons relay this information to higher olfactory centers, the mushroom body (MB), and lateral horn (LH). Local interneurons (LNs) mediate lateral interactions between different glomeruli. (Reprinted with permission from Jefferis, G.S.X.E., Marin, E.C., Watts, R.J., Luo, L., **2002**. Development of neuronal connectivity in *Drosophila* antennal lobes and mushroom bodies. *Curr. Opin. Neurobiol. 12*, 80–86; © Elsevier.)

sensitivity of electrophysiological methods, or could perhaps be a species specific difference. In either case, it is certain that the precise formation of neuronal connections within the antennal lobe during development will have a strong influence on the information carried by output neurons and the potential for interactions among different channels of olfactory information.

After the initial relay, olfactory information passes to higher olfactory centers, located in the protocerebrum (see below), which are presumably involved in odorant recognition and discrimination, and the synthesis of olfactory memories. One structure in particular has received a great deal of attention: the mushroom body (MB; **Figure 1**). Ablation and inactivation experiments have suggested that the MB is required for olfactory learning and memory, but not for odorant detection *per se* (de Belle and Heisenberg, 1994; Connolly *et al.*, 1996). At the molecular level, *Drosophila* MBs show enriched expression of proteins involved in cyclic AMP signaling (Nighorn *et al.*, 1991; Crittenden *et al.*, 1998), some of which are encoded by genes inactivated in a series of learning mutants (review: Roman and Davis, 2001). Indeed, this significance of cAMP in the formation of memory has been echoed in many systems from *Aplysia* to mouse. Tissue specific rescues of learning mutants have shown that MB expression of these genes can be sufficient for learning (Zars *et al.*, 2000). Finally, experiments using reversible inactivation of synaptic transmission from mushroom body neurons to target neurons, have shown that this synaptic transmission is required for retrieval of memory, but not for learning (Dubnau *et al.*, 2001; McGuire *et al.*, 2001).

The representation of olfactory information within the MB has also been investigated electrophysiologically. One recent study in the locust, *Schistocerca americana*, has argued forcefully that olfactory information is sparsened in this structure; an olfactory stimulus, which might cause a large fraction of first and second order neurons to fire a large number of action potentials, caused a small number of neurons to fire a small number of spikes in the MB (Perez-Orive *et al.*, 2002). Finally, it should be emphasized that there is a large body of literature on nonolfactory functions of MBs, which in many insects are likely to act as a multimodal integrator in addition to any specific role in olfactory learning (Mushroom Body Special Issue, 1998).

In comparison, the function, physiology, and cellular composition (see below) of the other major target of olfactory information, the lateral horn (LH; **Figure 1**), remains more mysterious (e.g., de Belle and Kanzaki, 1999). At the functional level, it has been suggested that it may be required for experience independent olfactory behavior (Heimbeck *et al.*, 2001), although the evidence is indirect. Electrophysiology of the LH is less developed than any other part of the olfactory circuit discussed so far, although Perez-Orive *et al.* (2002) have identified an inhibitory neuronal feedback from the LH to the MB, which may be responsible in part for the sparsening of the olfactory representations described above.

Understanding how the multiglomerular representation typical of an individual odorant is transformed and decoded in higher olfactory centers remains one of the key questions in the physiology of the olfactory system.

1.12.2.2. Common Anatomy

1.12.2.2.1. Periphery The major olfactory appendages in most insects are a pair of antennae mounted on the head. In *Drosophila,* there are in fact two olfactory organs (**Figure 2a**), the third antennal segment and the maxillary palp, which is mounted on the proboscis; they contain about 1200 and 120 olfactory receptor neurons per hemisphere, respectively (Singh and Nayak, 1985; Stocker, 1994, 2001). Within the ORN, the site of signal transduction is the olfactory cilium, which is a specialized dendrite containing the olfactory receptor proteins (e.g., Elmore and Smith, 2001) and their transduction apparatus along with a prominent microtubule based cytoskeleton. ORNs are mounted in olfactory sensilla, which are the primary sensory structures (**Figure 3**) (see also **Chapter 1.11**).

Besides their neuronal component, which is typically in the range of 1–5 but can range up to more than 100, sensilla contain three support cells (**Figure 3**; review: Keil, 1999; **Chapter 1.11**): (1) the innermost thecogen or sheath cell, which wraps the neuron(s) in a glial fashion; (2) the hair cuticle-secreting trichogen or (hair) shaft cell, which contains pores through which odorants can diffuse; and (3) the tormogen or socket cell, which generates the base of the hair.

Sensilla may be classified based on their morphology into a number of different types, including basiconic (short and rounded), trichoid (long, thin), and coeloconic (short, in a pit, with a double cuticular wall), which are widely recognizable in different insect species . . . (see also **Chapter 1.11**) on sensillar development). The sensillar composition of the *Drosophila* antennae has been reviewed very comprehensively by Stocker (2001) (see also **Chapter 1.11**). Numbers vary somewhat according to strain and sex, but Stocker and Gendre (1988) report approximately 240 basiconic sensilla, 110 trichoid, and 70

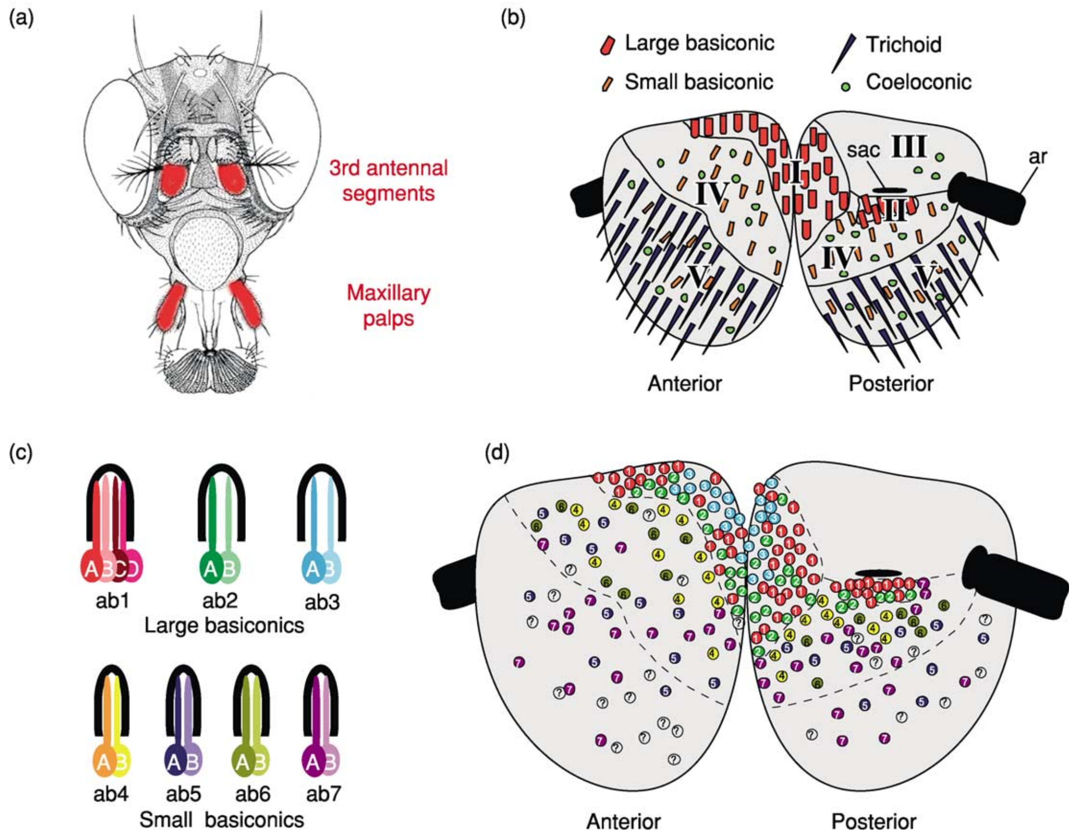

Figure 2 Location of sensory appendages and distribution of sensillar classes. (a) Frontal schematic of *Drosophila* head, showing the two pairs of sensory appendages, the third antennal segment, and the maxillary palp. (Reprinted with permission from Jefferis, G.S.X.E., Marin, E.C., Watts, R.J., Luo, L. **2002**. Development of neuronal connectivity in *Drosophila* antennal lobes and mushroom bodies. *Curr. Opin. Neurobiol. 12*, 80–86; © Elsevier.) (b) Zonal distribution of the major classes of olfactory sensillum (indicated by roman numerals I–V after de Bruyne *et al.*, 2001). Also indicated are the sacculus (sac) and the arista (ar). (c) The basiconic sensilla can be subdivided morphologically into large and small categories. These categories have been further subdivided into functional subtypes indicated by the different color hues (de Bruyne *et al.*, 2001). Within each sensillar subtype there is a unique combination of two or four olfactory receptor neurons, each with specific olfactory response profiles; recent work has correlated most response profiles with the expression of a particular olfactory receptor (Hallem *et al.*, 2004). (d) Distribution on the antenna of the seven basiconic subtypes defined in c. There is clear spatial clustering of different sensillar subtypes. ((b–d): Reprinted with permission from de Bruyne, M., Foster, K., Carlson, J.R., **2001**. Odor coding in the *Drosophila* antenna. *Neuron 30*, 537–552; © Elsevier.)

coeloconic on female antennae; males have 40 additional trichoids and 40 fewer basiconics. Counts of the maxillary palp suggested about 60 basiconic sensilla (Singh and Nayak, 1985).

Sensillar classes are differentially distributed on the antennal surface, with some populations in relatively homogeneous zones, while other areas contain a mix of different classes (**Figure 2b**; review: Stocker, 2001). Rather remarkably, sensillar classes appear to contain defined populations of OR. For example, in *Drosophila*, de Bruyne *et al.* (2001) have mapped the olfactory responses of the antennal basiconic sensilla. They identified seven classes of basiconic sensillum, each containing a stereotyped group of two or four ORNs with particular receptive ranges (**Figure 2c**). Thus, the choice of olfactory receptor must be coupled to the development of the sensillar morphology. Furthermore, these seven different basiconic sensillar classes were clustered in different domains on the antenna (**Figure 2d**), suggesting that there may be a coarse map of ORNs expressing different ORs on the antennal surface. Consistent with this, the ORs themselves are also spatially distributed in the antenna; however these distributions are overlapping, so that there is not a precise map of receptor expression on the sensory surface (Vosshall *et al.*, 1999, 2000). Whether a similar logic exists in other insects will become clearer as more olfactory receptor repertoires are characterized.

1.12.2.2.2. Antennal lobe ORN axons terminate in the CNS in the antennal lobe (in insects) or olfactory bulb (in mammals). Although these structures

may not share an evolutionary heritage (Strausfeld and Hildebrand, 1999), the organizational features are very similar. Morphologically, the key features are the glomeruli (**Figure 1**), spherical neuropil regions usually surrounded by a glial sheath. In many insects, these glomeruli appear to be stereotyped in size, shape, and relative position, so that atlases can be generated (e.g., *Drosophila*: Laissue *et al.*, 1999; *Apis*: Galizia *et al.*, 1999a; moths: Berg *et al.*, 2002). Glomeruli are the site of synaptic contact between three key neuronal types: ORN axons, PN dendrites (**Figure 1**; see also **Figure 4b**), and the processes of local interneurons (LNs; **Figure 1**) (review: Anton and Homberg, 1999). PNs and LNs are the major analogs of vertebrate mitral cells and granule cells, respectively. In *Drosophila*, ORNs and PNs usually synapse in single glomeruli, while LNs ramify through large areas of the lobe (Stocker *et al.*, 1990) (**Figure 1**); this organization is typical of most insects, but see Section 1.12.2.3 for variations on this theme. ORNs and most PNs are believed to use acetylcholine as a transmitter (review: Homberg and Muller, 1999); a subset of PNs whose axons project via the middle antenno-cerebral tract (mACT) (see Section 1.12.2.2.3 below) have been demonstrated to be GABAergic in a number of species including *Manduca*, *Apis*, and *Periplaneta* (review: Homberg and Muller, 1999). While LNs are largely GABAergic in most species (e.g., *Manduca*: Hoskins *et al.*, 1986; honeybee: Schafer and Bicker, 1986), there has

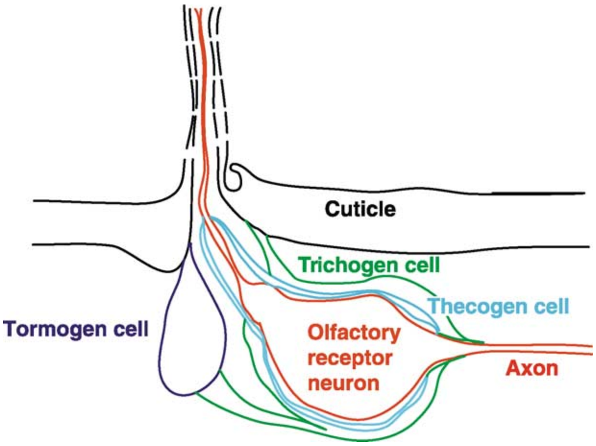

Figure 3 Schematic of the fine structure of an olfactory sensillum. A single olfactory receptor neuron is shown, although sensilla typically contain multiple neurons. The ORN is wrapped by the thecogen or sheath cell in a glial fashion. The outer pair of auxiliary cells, the trichogen (shaft) and tormogen (socket), secretes the main hair shaft and base, respectively. The ORN dendrite innervates the shaft space, where it is bathed in a sensillar lymph. Small pores in the shaft cuticle allow odorants to enter and contact the ORN.

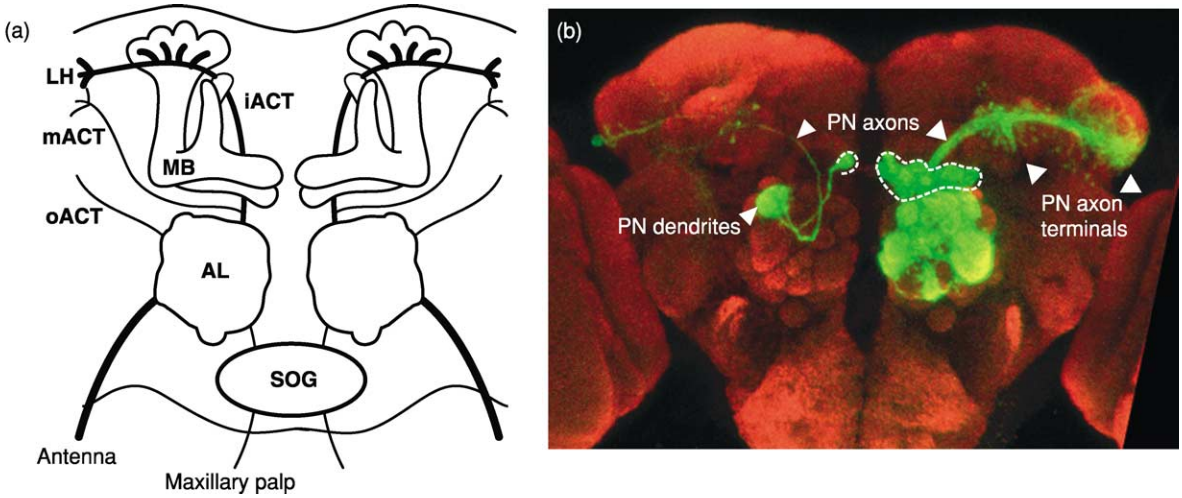

Figure 4 Schematic of the olfactory anatomy of the insect brain. (a) Frontal view of the *Drosophila* brain (the same orientation as the head in **Figure 2a**). Olfactory information arrives from the antenna, with a minor afferent from the maxillary palp taking a different route through the subesophageal ganglion (SOG), and terminates in the antennal lobe (AL) glomeruli. Projection neuron axons relay that information to the calyx of the mushroom body (MB) and/or the lateral protocerebrum via three major antenno-cerebral tracts (ACTs). Uniglomerular cholinergic PNs of the inner ACT are the most numerous and project both to the MB calyx and the lateral horn (LH) of the protocerebrum. PNs employing the middle ACT are usually GABAergic and project generally to the lateral protocerebrum. The outer ACT contains PNs that project to the inferior lateral protocerebrum. (b) Example of a labeled single cell and a group of projection neurons generated using the MARCM method (review: Lee and Luo, 2001). The single cell labeled using a membrane targeted green fluorescent protein has a cell body (dotted line) from which a neurite extends, connecting to a dendritic arbor that innervates the glomerulus DL1 and an axon that projects through the iACT to the mushroom body calyx and lateral horn. An antibody recognizing synaptic structures (red), reveals the general organization of the brain, including the glomeruli of the antennal lobe. (Reproduced with permission from Jefferis, G.S.X.E., Marin, E.C., Stocker, R.F., Luo, L., **2001**. Target neuron prespecification in the olfactory map of *Drosophila*. *Nature 414*, 204–208; © Nature Publishing Group.)

been no formal demonstration of this in *Drosophila*, although GABA receptors are present in the glomeruli (Aronstein and ffrench-Constant, 1995).

The synaptic connectivity within glomeruli has perhaps been most studied in the cockroach, *Periplaneta americana* (review: Distler and Boeckh, 1998). There are extensive synaptic connections between the three different neuronal cell types, such that PNs receive input from ORNs and LNs, while LNs are postsynaptic to ORNs, PNs, and LNs. Finally, it appears that LNs can make connections back to ORNs (review: Distler and Boeckh, 1998). The existence of these direct, indirect, and feedback pathways is likely at the origins of the oscillatory phenomena investigated most especially in the locust, *S. americana* (review: Laurent, 2002).

Besides the neurons in the AL, there are of course glia, which wrap the whole AL and send processes into it. It should be noted that the extent of glial processes within the lobe varies widely among different insects, with substantial glial presence in moths and bees (Boeckh and Tolbert, 1993; Hahnlein and Bicker, 1996), but little glia in flies and cockroaches (Stocker *et al.*, 1990; Boeckh and Tolbert, 1993). In the mature organism, glial cells are likely to have a metabolic role, for example, in neurotransmitter cycling (Hahnlein and Bicker, 1996); however, they have also been shown to be of great significance for antennal lobe development in some species (see Section 1.12.4 below; review: Oland and Tolbert, 2003).

1.12.2.2.3. Antenno-cerebral tracts Output from the antennal lobe is directed to the protocerebrum; the two major targets are the calyx (or dendritic field) of the mushroom body and the lateral horn, although there are additional terminations in the other regions of the protocerebrum. PN axons course through a number of antenno-cerebral tracts (ACT) to reach these higher olfactory centers (Kenyon, 1896) (**Figure 4a**).

The major tracts and their PN constituents can be clearly identified in a number of insect species (review: Anton and Homberg, 1999) and here the nomenclature used in *Drosophila* (Stocker *et al.*, 1990; Stocker, 1994) and *Manduca sexta* (Homberg *et al.*, 1988) is followed. The largest tract is the inner antenno-cerebral tract (iACT; **Figure 4**), through which a population of largely uniglomerular PNs send axons first to the MB, where collaterals form synapses in the calyx, and then to the LH. Two smaller tracts, the mACT (middle ACT) and oACT (outer ACT), are also widely identifiable (**Figure 4**). PNs employing these tracts seem to be more heterogeneous. The mACT PNs are frequently multiglomerular and project to the LH or through large areas of the superior or lateral protocerebrum. The oACT neurons are even more diverse, typically have multiglomerular innervation in the antennal lobe, and may terminate in the lateral protocerebrum including the LH, the superior protocerebrum, and the MB calyx, or even cross over to the contralateral hemisphere (Homberg *et al.*, 1988). Observations in *Drosophila* are consistent with these general organizational principles (Stocker *et al.*, 1990; Marin *et al.*, 2002; Wong *et al.*, 2002).

1.12.2.2.4. Mushroom body (MB) The neuronal architecture of the protocerebrum in insects is, in general, rather less understood than the deutocerebrum, the site of the antennal lobe. One clear exception is the mushroom body, an intensively studied structure first identified by Dujardin (1850). The MBs are bilaterally symmetric, densely packed neuropils. Each consists of a large number of Kenyon cells (KCs) or intrinsic MB neurons, which form a dendritic field, the calyx (often cup-shaped), and then course down the peduncle before bifurcating into two perpendicular lobes, the medial α and dorsal β lobes (**Figure 5**). There are large input synapses in the calyx; in the lobes, there are both en-passant axo-axonal synapses as well as output structures.

In *Drosophila*, there have recently been significant advances in our understanding of the fine structure of the MB. The bilobed MB structure turned out to encompass five discrete lobes, two dorsal (α, α') and three medial (β, β', γ) (Crittenden *et al.*, 1998). These different lobes could be identified by a number of different antigenic markers including the cell adhesion molecule Fasciclin II (FasII) (Crittenden *et al.*, 1998) (**Figure 5**). Cellularly, three distinct kinds of cells underlie this diversity of lobes: two forms with branched axons, $\alpha\beta$ and $\alpha'\beta'$ neurons, and unbranched γ neurons (Lee *et al.*, 1999). Further subdivisions have recently been noted by Strausfeld *et al.* (2003). Indeed an earlier study had shown that MB neurons are much more molecularly heterogeneous than previously anticipated, since enhancer trap techniques can reliably label distinct populations of MB neurons from individual to individual (Yang *et al.*, 1995).

Recently, Yasuyama and colleagues (Yasuyama *et al.*, 2002) using the electron microscope looked at the ultrastructure of the MB calyx in some detail. They concluded that synaptic organization is glomerular: cholinergic PNs terminate in a large bouton (2–7 μm diameter), which makes presynaptic contacts with a large number of postsynaptic MB neuron dendrites. Presynaptic GABAergic neurons

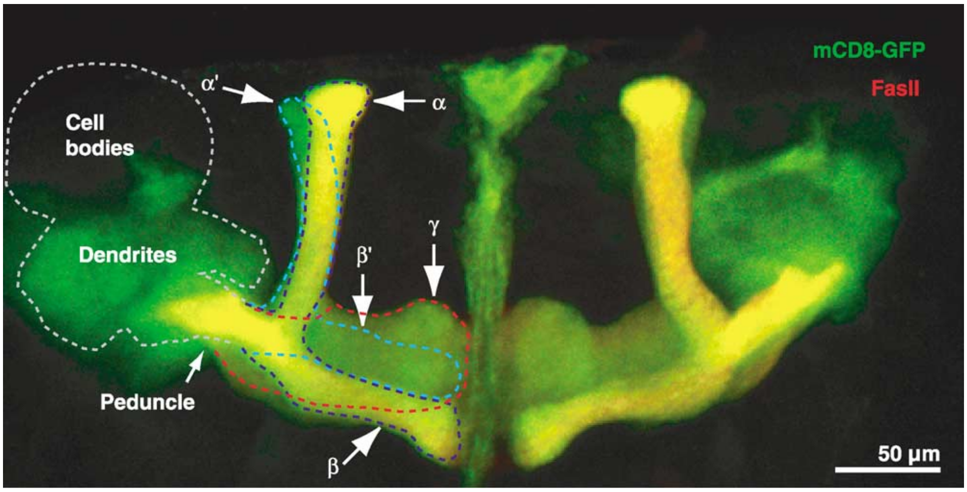

Figure 5 Structure of the *Drosophila* MBs revealed by membrane targeted GFP (mCD8-GFP, in green) driven by an enhancer trap line expressed in most MB neurons (*GAL4-OK107*). FasII (red) is strongly expressed in the α/β lobes, weakly in the γ lobe and not detectable in the α′/β′ lobes. The midline is marked with a dashed white line; dorsal is uppermost. (Reprinted with permission from Jefferis, G.S.X.E., Marin, E.C., Watts, R.J., Luo, L., **2002**. Development of neuronal connectivity in *Drosophila* antennal lobes and mushroom bodies. *Curr. Opin. Neurobiol. 12*, 80–86; © Elsevier.)

are also associated with these glomeruli, and make contact both with MB neurons and occasionally with the cholinergic bouton itself. Extrinsic neurons, which will now be described, are candidates for this GABAergic input.

The connectivity of extrinsic neurons of the MBs is, in general, less understood (but see Ito *et al.*, 1998). This probably reflects their much more heterogeneous character and more diffuse projection patterns. At least four general classes of extrinsic neurons can be considered: input neurons, output neurons, feedback neurons, and neuromodulatory neurons. PNs are the most obvious class of input neuron, but there are others including feedback neurons originating in the lateral horn (see Section 1.12.2.2.5 below).

Extrinsic output neurons have been described with projections to the lateral protocerebrum; for example, in the honeybee, Rybak and Menzel (1998) have characterized the Pe1 neuron, which shows multimodal responses (see Section 1.12.2.3.3 below for a description of multimodal input to MBs) including transient olfactory responses dependent on learning state. GABAergic (and presumably inhibitory) feedback neurons have been described that connect the medial and dorsal branches of the MB or that connect the lobes with the calyx (Rybak and Menzel, 1993). A second class of neurons that may have feedback properties are bilateral neurons, which connect mushroom body lobes in each hemisphere.

Finally, there are neuromodulatory neurons, containing transmitters like serotonin and octopamine. The two most spectacular examples are the ventral unpaired medial (VUMx1) neuron identified in honeybees, and the dorsal paired medial (DPM) neurons present in *Drosophila*. The VUMx1 neuron is an octopaminergic neuron with a cell body at the midline of the subesophageal ganglion (SOG), which includes the termination zone of gustatory neurons. VUMx1 has bilateral dendritic arborizations within the SOG and dense axonal arborizations in the ALs, MB calyces, and LH (Hammer and Menzel, 1995). Sucrose stimulation of the proboscis causes the neuron to fire. Remarkably, depolarization of the neuron can substitute for sucrose in a classical conditioning paradigm, in which an odorant (conditioned stimulus; CS) paired with sucrose (unconditioned stimulus; US) could subsequently cause US-independent extension of the proboscis (Hammer, 1993). Firing of VUMx1 thus appears to act as a reinforcer in this associative learning.

The DPM neurons are a pair of large unilateral neurons with extensive arborizations in the mushroom body lobes. They have been identified as the highly enriched site of expression of the neuropeptide encoded by the *amnesiac* (*amn*) gene in the brain (Waddell *et al.*, 2000). In contrast to VUMx1, DPM neurons appear to play a role not in the associative learning process, but in the consolidation of memory. The *amnesiac* mutant flies, or flies in which the DPM neurons are transiently inactivated, can learn an olfactory association normally, but then have no memory whatsoever after 1 h (Waddell *et al.*, 2000). It should be noted that the anatomy of both VUMx1 and DPM neurons is consistent with their physiology. In the case of

VUMx1, relaying a gustatory signal from the SOG to diffuse contacts in higher olfactory centers may allow connections with the many potential olfactory neurons that could become active in response to the panoply of different potential CS odorants. In the case of DPMs, the memory consolidation phase is believed to occur in the intrinsic neurons of the MB.

1.12.2.2.5. Lateral protocerebrum and lateral horn The structure of the lateral protocerebrum (LPR), in general, and, in particular, that of the lateral LH, an ovoid structure in the most lateral portion of the protocerebrum, remains relatively poorly understood. Among input neurons, certain classes of PNs, already mentioned in Section 1.12.2.2.3 above, have been well described (see also **Figure 4**). Furthermore, two recent studies in *Drosophila* have provided significant new information (Marin *et al.*, 2002; Wong *et al.*, 2002). These new studies, which employed genetic single cell labeling techniques, described in great detail the axonal projection patterns of a significant fraction (perhaps one-third) of the repertoire of *Drosophila* PNs. They both conclude that PNs, whose dendrites innervate a particular glomerulus, show highly stereotyped axonal projections in the lateral horn. These axonal branching patterns are more widespread than the corresponding dendritic arborizations in individual glomeruli of the antennal lobe. These two observations indicate both a convergence and a divergence of olfactory information.

Other input neurons that innervate the lateral horn include some of the extrinsic neurons of the mushroom body (e.g., the Pe1 neuron mentioned in Section 1.12.2.2.4 above) and neuromodulatory neurons, for example, the octopaminergic VUMx1 neuron also mentioned above.

The output neurons of the lateral horn are at present rather poorly cataloged. One exception is a group of GABAergic neurons, which have been identified in the locust (Laurent and Naraghi, 1994). These form a strong connection back to the mushroom body calyx (Perez-Orive *et al.*, 2002).

A first attempt to describe the ultrastructure of the lateral horn has recently been made in *Drosophila* by Yasuyama *et al.* (2003), who found that cholinergic synapses of afferent PNs are usually presynaptic to a large number of noncholinergic profiles. Sometimes, PN terminals appeared as postsynaptic spines to large noncholinergic interneurons, which may perhaps be the GABAergic neurons described above.

1.12.2.3. Anatomical Variations

1.12.2.3.1. Antennae The antennae of insects show a huge variation in size, morphology, and other functional specializations (Schneider, 1964; Keil, 1999). Antennae may have a simple flagellar form very typical in hemimetabolans, which must pass through successive molts to reach the adult form. In holometabolans, which have the opportunity to resculpt their antennae during metamorphosis, much more elaborate structures can be observed – perhaps most dramatically, the so-called pectinate (or feather shaped) antennae of certain moths, which dramatically increase the receptive surface area. Other specializations may include antennal mobility. Ants, for example, have highly mobile antennae, which they use when following pheromone trails or other chemical cues and when identifying nestmates or prey (Holldobler and Wilson, 1990). Finally, marked intraspecies differences can also be observed, including the well-known specializations of the antennae of some male moths (especially Saturniids) for detecting female pheromones.

Antennal specializations are not limited to males: for example, female *A. stephensi* have up to three times more ORNs than their male counterparts, which is believed to reflect their requirement to seek out hosts for blood meals (McIver, 1982).

1.12.2.3.2. Antennal lobe (AL) There are large variations in the number and morphology of glomeruli in the AL. For example, *Aedes aegypti* has only 32 glomeruli (in either sex), while in locusts there may be as many as 1000 small glomeruli. This large number of glomeruli in locusts is, in fact, unusual among all insect species examined, and there is a matching difference in the morphology of ORN and PN projection patterns. Locust ORNs project their axons to multiple glomeruli (Hansson *et al.*, 1996), typically 1–3 according to Laurent (1996), while PNs project dendrites to around 10–20 glomeruli, which may be some distance apart in the lobe (Laurent and Naraghi, 1994; Anton and Hansson, 1996). Whether this pattern reflects a divergence of olfactory information from a single OR type, followed by a reconvergence of that same information in a matched population of PNs, is not clear.

Within species, there are clear examples of sexual dimorphism in the lobe. In many species, the male has a group of dramatically enlarged glomeruli near the entry point of the antennal nerve into the AL, the macroglomerular complex (MGC) in moths, which are the target of sex pheromone responsive ORNs (Hildebrand, 1995). Although it was originally assumed that these glomeruli were novel in the male and did not have homologs in the female, a recent high-resolution study of the AL in *M. sexta* (Rospars and Hildebrand, 2000) has found a similar number

of female-specific glomeruli and attempted to define homologies with the components of the MGC. Conversely, an imaginative comparative study in *D. melanogaster*, a species in which no sexual dimorphism had previously been reported, has identified two of the "ordinary" glomeruli as sexually dimorphic (Kondoh *et al.*, 2003).

A final anatomical variation of note is the existence in dipterans of a commissure joining the two antennal lobes; this tract is populated by the axons of ORNs, which, in these species, project both to an ipsilateral glomerular target and to its contralateral homolog (Stocker *et al.*, 1990). In *Drosophila*, there is also a population of local interneurons with projections across the midline to the contralateral AL, which may be cholinergic (unpublished results cited in Stocker and Rodrigues, 1999).

1.12.2.3.3. Tracts and higher centers Besides the three ACTs joining the AL to the protocerebrum (Section 1.12.2.2.3), a number of additional, smaller tracts have been identified in some insects, e.g., dACT and dmACT in *M. sexta*, which innervate the lateral horn and mushroom body calyx/lateral horn, respectively. Whether these tracts are also present in other insects remains unclear but, in general, the conservation of anatomical features at this level is quite impressive.

The MB has received a great deal of attention in many insect species, so there is a substantial amount of comparative data on its structure (review: Strausfeld *et al.*, 1998). Potential variables include the number of intrinsic MB neurons, the diversity in the incoming neuronal information, the size and structure of the calyx, and the existence of much enlarged or additional lobes. MB neuronal number varies widely among insect species – for example, *Drosophila* has an estimated 2500 neurons per side, *Musca* approximately 21 000, while honeybee drones have about 170 000 and male cockroaches (*P. americana*) upwards of 200 000 (review: Schurmann, 1987). Furthermore, this neuronal number does not vary uniformly with brain size; for example, MBs are relatively enlarged in highly social insects, such as bees, prompting Dujardin, their original discoverer, to propose them as the seat of insect intelligence (Dujardin, 1850).

Regarding morphology, Strausfeld *et al.* (1998) argue that the ancestral form of the MB may have been without a calyx; the extensive olfactory input would therefore be a later addition. Dipterans such as *Musca* and *Drosophila* have roughly ovoid calyces with few externally obvious morphological features. In contrast, other species have highly developed calyces, such as the honeybee, whose calyces are a pair of cup-shaped substructures with distinct spatial patterns of innervation for olfactory, visual, and gustatory input (Menzel *et al.*, 1994); similar findings exist for the cockroach (Nishikawa *et al.*, 1998). Anatomical studies of olfactory protocerebral regions besides the MBs are really too incomplete for comparative work to distinguish species' differences from simple lack of information.

1.12.2.3.4. Larval olfactory system Holometabolous insects with a larval form typically have a functional olfactory system by the time they hatch. The olfactory world faced by this system may be quite different from that encountered later by the adult and, consequently, the structure of the two olfactory systems might also be expected to differ. In general, larval olfactory systems have been characterized as numerically and organizationally simpler than their adult counterparts. For example, in both *Drosophila* and *Apis mellifera*, the larval antennal lobes (ALs) appear aglomerular (Masson and Arnold, 1984; Gascuel and Masson, 1991). However, in other species including the monarch butterfly, *Danaus plexippus*, and *M. sexta*, a nodular organization of the larval antennal lobe has been observed (Nordlander and Edwards, 1970; Kent and Hildebrand, 1987).

Recent studies in *Drosophila* suggest that the organizational complexity of this larval system may have been underestimated. A high resolution study by Python and Stocker (2002) finds that, in spite of the massively reduced number of incoming ORNs (approximately 21 in the larvae versus 1300 in the adult), the antennal lobe appears to have approximately 30 distinct subdivisions, reminiscent of adult glomeruli.

The cloning of a second chemosensory receptor gene family in *Drosophila*, termed gustatory receptors (GRs; although not all of these receptors appear to serve a gustatory function), had previously allowed tracing of some larval afferents to the antennal lobe (Scott *et al.*, 2001b). These authors concluded that individual classes of larval ORN terminated in discrete subregions of the antennal lobe. Python and Stocker (2002) also described a population of larval PNs labeled by the enhancer trap line GH146 (Stocker *et al.*, 1997). Single cell labeling studies have established that individual PNs have dendritic arborizations corresponding to the presumed larval glomeruli, and project to the calyx of the larval MB and LH. One novel finding is that in the larva, PNs project focally to discrete "glomerular" structures in the MB calyx, rather

than terminating at multiple sites (E.C. Marin and L. Luo, unpublished data; A. Ramaekers, N. Gendre, and R.F. Stocker, unpublished data).

Local interneurons are also present in the larval lobe, as demonstrated morphologically by examining enhancer trap lines, and immunohistochemically, by the use of anti-GABA antibodies (Python and Stocker, 2002). A single serotonin-containing neuron and octopamine-containing neurons were also detected. Overall, the structure of this particular larval olfactory system appears to be hybrid in character. Olfactory information is transduced by a dramatically reduced number of sensory neurons in the periphery, but nevertheless projects with very similar logic to the antennal lobe, before being relayed by PNs (that will persist and serve an identical function in the adult) to the MB and what appears to be a larval lateral horn.

1.12.3. Development of the Peripheral Olfactory System

1.12.3.1. Generation of Sensilla Including Olfactory Receptor Neuron Neurogenesis

In all holometabolous insects, antennae derive from imaginal discs, which exist in the larval stage as flattened pouches of undifferentiated epithelial cells set aside for later use. Here the focus is on the generation of the individual sensory units, the sensilla, from the initially unpatterned disc epithelium; for further information (see also **Chapter 1.11** on sensillar development). The formation of external sensory organs (of which olfactory sensilla are an example), and most particularly mechanosensory bristles, has been well studied in a large variety of insects. The general mode of development is the selection from cells in the epithelial field of sensory organ precursors (SOPs). Each SOP is usually selected out from one of the many proneural cell clusters in the epithelium – typically one cell within each cluster adopts the SOP fate and delaminates from the epithelium. The SOP then undergoes a small number of stereotyped asymmetric divisions to generate the different cell types within each sensillum (Jan and Jan, 1993).

Comparative studies have suggested that these lineages are rather conserved between similar sensory organs in different species (Bate, 1978), and that basic patterns of division may be reiterated with small variations in the generation of different kinds of sensory organs (Bellaiche and Schweisguth, 2001). This lineage-based generation of sensilla is in marked contrast to the generation of the photoreceptors of the compound eye, which proceeds by the sequential recruitment of neighboring cells via cell–cell interactions initiated by a founder cell (Dickson and Hafen, 1993).

There are several general themes in the developmental biology of external sensory organs. (1) How are the number, spacing, and position of SOPs controlled? Key mechanisms are the existence of prepatterns of proneural clusters (defined by the expression of bHLH transcription factors) in some epidermal fields (reviews: Simpson, 1997; Simpson *et al.*, 1999), and the employment of lateral inhibition via the Notch pathway. (2) What is the relative importance of lineage versus recruitment? (3) How are different subtypes of sensillum generated, particularly different neuronal types (for a general review of proneural genes and subtype specification, see Bertrand *et al.*, 2002)? (4) How does the SOP divide asymmetrically to generate different cell fates (review: Jan and Jan, 2001)? Some of these themes are addressed specifically in the generation of olfactory sensilla in *Drosophila*.

In *Drosophila,* the antennal imaginal discs are quite separate from the larval sensory structures, and already present as a group of 7–9 progenitor cells set aside in the embryo 2 h after egg laying (Postlethwait and Schneiderman, 1971). No further division takes place until 24 h after larval hatching (Madhavan and Schneiderman, 1977), when exponential growth proceeds through the remaining 4 days of larval life, so that there are about 2500 cells per disc at pupation (Postlethwait and Schneiderman, 1971). Around this time, differentiation of the epidermal field of the antennal disc begins and there is a halt in proliferation.

The concentric organization and development of the antennal imaginal disc has been described by Haynie and Bryant (1986). Precursor cells that will generate the third antennal segment (3AS) occupy a central location. These cells are surrounded by precursors of the second antennal segment (containing, in *Drosophila*, the auditory Johnston's organ) and, finally, at the periphery, by the first antennal segment precursors. During pupal metamorphosis, which lasts approximately 100 h in *Drosophila*, the antennal disc, like other imaginal discs, will telescope out so that the central regions become the most distal.

SOP specification and delamination occurs in three major waves (**Figure 6**) (Ray and Rodrigues, 1995; zur Lage *et al.*, 2003), which can be visualized by expression of the *senseless* (*sens*) gene (Nolo *et al.*, 2000). The first wave appears a few hours before puparium formation and consists of a well-spaced semicircle of SOPs at the periphery of the 3AS zone of the antennal disc. The second wave appears by 4 h after puparium formation (APF). It is more numerous, more centrally located, and consists of

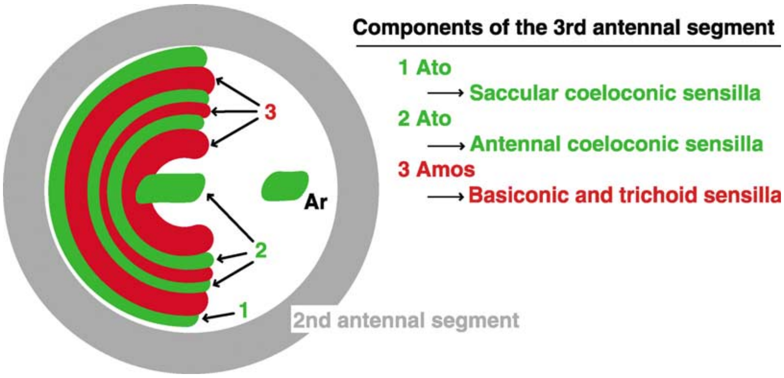

Figure 6 Three waves of sensory organ precursors (SOPs) generate the *Drosophila* olfactory sensilla. Peripherally located wave 1 SOPs express Ato, have appeared by 0 h APF, and generate the coeloconic sensilla of the sacculus. Wave 2 SOPs, which also express Ato, appear by 4 h APF, are more numerous, and arranged in three semicircular rows; these give rise to the coeloconic sensilla of the third antennal segment. Amos expressing wave 3 SOPs are much more numerous. They initially appear to intercalate between the Ato expressing semicircles, but then expand in number. These SOPs give rise to the more numerous basiconic and trichoid sensilla. An additional Ato dependent group, which gives rise to aristal sensilla (Ar), is also marked. (Redrawn with permission from zur Lage, P.I., Prentice, D.R., Holohan, E.E., Jarman, A.P., **2003**. The *Drosophila* proneural gene amos promotes olfactory sensillum formation and suppresses bristle formation. *Development 130*, 4683–4693.)

a stereotyped pattern of cells including two semicircles. Both of these waves of SOPs express the proneural gene *atonal* (*ato*), which is also required for the formation of chordotonal organs (Jarman *et al.*, 1993) and photoreceptors (Jarman *et al.*, 1994), and appear to be derived from *ato* expressing proneural clusters in the overlying epithelium (Jhaveri *et al.*, 2000a; zur Lage *et al.*, 2003). Both are absent in *atonal* mutant antennae and functionally will generate sensilla coeloconica of the sacculus (wave 1) and the main antennal surface (wave 2) (**Figure 6**) (zur Lage *et al.*, 2003). In contrast to these first two waves, *amos* expressing SOPs derived from overlying Amos positive proneural clusters, appear in a third wave first evident at 8 h APF. These SOPs initially intercalate between the wave 2 *ato*-dependent SOPs. However, by 16 h APF these *amos* SOPs are much more numerous and less obviously spatially patterned.

zur Lage *et al.* (2003) were able to identify an *amos* enhancer whose expression was maintained in SOP progeny, which turned out to be all cells in the sensilla basiconica and trichodea; this is satisfyingly consistent with the *amos* loss-of-function phenotype, which is a complete loss of sensilla basiconica and trichodea (zur Lage *et al.*, 2003).

In short, the generation of the different SOPs responsible for the three classes of olfactory sensilla has now been established with some precision and conforms, in general, to the expected norms of sensory organ development. However, the next step, which would normally be the stereotyped division of the SOPs, remains somewhat less clear. Mitotic cells are not detected in the 3AS zone of the disc until about 12 h APF and, even then, they are in the periphery of the lobe, corresponding to wave 1 cells, which delaminated at least 12 h earlier (Sen *et al.*, 2003). In the meantime, it seems that the SOPs (or, more appropriately, founder cells) recruit additional neighboring cells to form a presensillum cluster (PSC) of 2–3 cells, which can be labeled by the A101 (*neuralised; neu*) enhancer trap (Reddy *et al.*, 1997). This conclusion was supported both by BrdU labeling, with no division detected between the generation of SOPs and the formation of PSCs (Ray and Rodrigues, 1995), and by clonal analysis (Reddy *et al.*, 1997). Clones were generated at mid first larval instar, i.e., very early in antennal disc formation, and then analyzed at 48 h APF, i.e., mid-pupal stage, in principle after the final division of sensillar progenitors (see below). In all 29 sensillar clusters analyzed, clonal boundaries separated cells of the same sensillum. This unusual mode of PSC development is similar to the recruitment of neighboring cells by R8 photoreceptors, which, incidentally, are also *ato* dependent like waves 1 and 2 olfactory SOPs. Reddy *et al.* (1997) confined their studies to those SOPs generated within the first 10 h of larval development. It will be very interesting to determine if the more numerous *amos* dependent SOPs of the third wave show a similar behavior.

After the formation of the PSC, these cells finally divide at least once to generate the sensillar components (**Figure 7**). This period of division is reported by Sen *et al.* (2003) to last from 12 to 22 h APF. Sen *et al.* (2003) have identified at least three different division patterns by analysis of clones generated at 10 h APF, i.e., before division starts, and analyzed

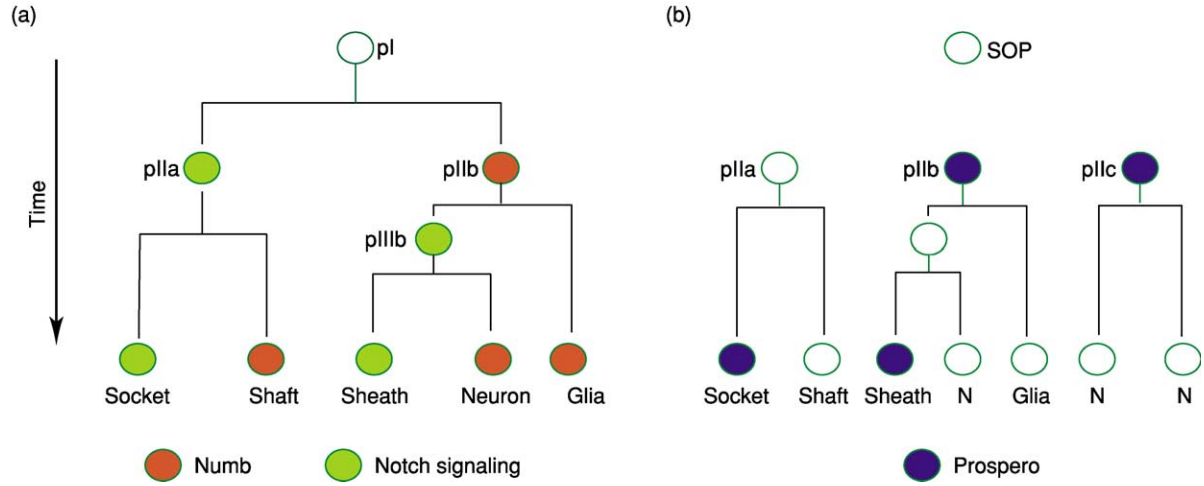

Figure 7 Lineages of the mechanosensory and olfactory sensilla in the *Drosophila* PNS. (a) Generalized lineage of the mono-innervated sensilla of the *Drosophila* PNS, illustrated for the adult microchaete lineage (review: Bellaiche and Schweisguth, 2001). Numb (red) or Notch signaling (green) show asymmetric segregation at each division. pI, pII, and pIII refer to the precursors of three successive stages of division. (b) Lineage of the olfactory sensilla proposed by Sen *et al.* (2003). Note the close correspondence between the products of the pIIa and pIIb division in this lineage and that in (a). N, neuron; SOP, sensory organ precursor.

at 36 h APF, i.e., after division ends (**Figure 7b**). Two of these patterns are directly analogous to the division pattern of the adult sensory bristle (**Figure 7a versus b**) and are named accordingly. The pIIa precursor generates the socket and shaft accessory cells, while pIIb generates a migratory glial cell and another intermediate, pIIIb, which gives rise to a neuron and the sheath (the most glial-like of the sensillar accessory cells). In fact, only the *ato*-dependent coeloconic sensilla show the full pIIb lineage, since they are gliogenic (Jhaveri *et al.*, 2000b). The corresponding PSC cells in the trichoid and basiconic lineages, which are nongliogenic, may proceed directly to the pIIIb division, or the equivalent of the glial cell could undergo apoptosis. Finally, there is a division pattern labeled pIIc by Sen *et al.*, (2003), which generates a pair of neurons.

In short, it is proposed that the generation of olfactory sensilla follows a hybrid pattern, in which the newly selected SOP recruits neighbors, rather than undergoing an initial division, but this cluster of cells then divides in a manner typical of other sensory organ lineages. It is possible that such a system allows more flexibility in the generation of sensilla with different numbers of ORNs, perhaps by the recruitment of 0, 1, or 2 cells, which will undergo the neurogenic pIIc division pattern.

1.12.3.2. Specification and Differentiation of Sensilla and ORNs

How are SOPs and their progeny specified to adopt different sensillar fates? The proneural genes *ato* and *amos* are clearly necessary for the coeloconic and basiconic/trichoid fates, respectively. Are they also sufficient to specify these alternatives? In addressing this question it should first be noted that ectopic Ato expression in other contexts leads to the formation of chordotonal organs (Jarman *et al.*, 1993), while ectopic Amos expression outside olfactory SOPs leads to formation of mechanosensory bristles (Lai, 2003; zur Lage *et al.*, 2003). Consequently, there must be additional factors within the olfactory SOPs or in other lineages that cooperate with the proneural genes. Jhaveri *et al.* (2000a) have investigated whether *ato* may be sufficient to direct coeloconic formation in the context of olfactory SOPs. By expressing Atonal in SOPs and their progeny with the A101 neu-GAL4 enhancer trap mentioned earlier, they were able to show a substantial increase in the number of coeloconic sensilla and a concomitant reduction in trichoid and basiconic numbers. The additional coeloconic sensilla were located in a domain on the antenna normally rich in basiconic sensillar, further supporting the notion of conversion. Besides differences due to these two proneural genes, there must also be mechanisms to differentiate the future trichoid and basiconic sensilla among the Amos expressing SOPs. Gupta *et al.* (1998) have suggested a role for *runt* (*run*) in this choice.

After the final division of sensillar components (described in Section 1.12.3.1 above), when do sensilla and, in particular, their constituent ORNs begin to differentiate? In *Drosophila*, various markers have been used to follow the differentiation of neurons in the peripheral nervous system (PNS)

including the monoclonal antibody mAb22C10 (Zipursky *et al*., 1984), which detects the microtubule associated protein, Futsch (Hummel *et al*., 2000). Lienhard and Stocker (1991) reported the appearance at 14 h after APF of three clusters of about 5–8 mAb22C10 positive neurons in the developing 3AS, which they labeled t1–t3. Since other molecular markers were unavailable at that time, correspondence with the more recent results obtained by zur Lage *et al*. (2003) on SOP formation is difficult. However, Lienhard and Stocker (1991) argued that t3 corresponds to a basiconic group (since it is absent in the *lozenze*^{3} (*lz*^{3}) mutant, which completely lacks basiconic sensilla), while the others are likely to be coeloconic. Thus, the *ato* dependent neurons of the first two waves described by zur Lage *et al*. (2003) probably correspond to t1–t2, while t3 may correspond to products of the first *amos* dependent SOPs. The number of mAb22C10 positive neurons in each cluster increases rapidly by 19 h APF and, in addition, further neurons appear between the clusters (likely to correspond to progeny of the wave of expansion of *amos* dependent SOPs between 8 and 16 h APF), so that by 26 h APF, the organization strongly resembles that of the adult. Ray and Rodrigues (1995) also described the development of mAb22C10 staining. They found that at 14 h APF mAb22C10 stains one or two cells in each presensillum cluster, i.e., mAb22C10 can also stain neural precursors (Hartenstein and Posakony, 1989). By 20 h APF, approximately 140 sensilla have adopted a mature mAb22C10 pattern according to Ray and Rodrigues (1995). Since there are approximately 70 coeloconic sensilla (see Section 1.12.3.1), this number should include some of the *amos* dependent basiconic or trichoid sensilla.

zur Lage *et al*. (2003) have reported that ORNs generated by *amos* dependent SOPs differentiate later than their *ato* dependent counterparts. At 24 h APF mAb22C10 labeling of neuronal processes is widespread throughout the 3AS (presumably corresponding to *ato* dependent coeloconic sensilla), while it is conspicuously absent from sensilla derived from *amos* SOPs. By 30 h APF, differentiation of the two outer cells (socket and shaft) has occurred in many of the *amos* dependent sensilla, which can therefore be identified as basiconic or trichoid. This absence of mAb22C10 staining in any sensilla derived from *amos* dependent SOPs at 24 h APF seems to contradict the number of mature mAb22C10 positive cells reported by Ray and Rodrigues (1995) at 20 h APF. There is no obvious explanation for this discrepancy, although it is possible that the amos-GAL4 enhancer generated by zur Lage *et al*. (2003) is not expressed in all *amos* dependent SOP lineages.

In attempting to connect the development of ORNs and their olfactory function, one of the key questions that must be addressed is how they come to express specific olfactory receptors. This remains an open question. For example, it is not yet clear at what stage ORNs become specified to express a particular odorant receptor (OR) type. OR expression has only been reported after 54 h APF in *Drosophila* (Clyne *et al*., 1999b), which is more than 1 day after ORN axons and projection neuron (PN) dendrites first meet. Nor is the relationship between control of sensillar type and OR expression clear. It is possible that individual SOPs are specified right from the time of their delamination to generate ORNs expressing a particular subset of receptors. The electrophysiological recordings of de Bruyne *et al*. (2001) suggest that basiconic sensilla contain only stereotyped pairings of ORNs expressing different OR types. If the recruitment hypothesis (Ray and Rodrigues, 1995; Reddy *et al*., 1997) is correct and applicable to all sensilla, then there must be a tight coupling between the fates of the daughters of the different members of the presensillum cluster. This would require that neighboring cells also have a precisely defined potential that the founder cell somehow signals instructively to indicate the exact nature of the appropriate OR choices for that sensillum. Alternatively, a choice of OR in one ORN within a sensillum could influence the OR choice of the other ORNs. Any of these possibilities would suggest rather precise intercellular signaling events, whose elucidation is awaited with much interest.

There is one additional piece of molecular data that may offer an opening into the OR/ORN specification problem. At the same time that Clyne *et al*. (1999b) were characterizing the olfactory receptor family of *Drosophila* (see Section 1.12.2.1.1), they were also working to characterize a long-standing behavioral mutant, *abnormal chemosensory jump 6* (*acj6*). The *acj6* mutant was one of a series of mutants isolated in an olfactory behavioral screen approximately 10 years earlier (McKenna *et al*., 1989). The *acj6* mutants did not respond to a subset of odorants, and an abnormal electroantennogram suggested that the defect was likely to be peripheral (Ayer and Carlson, 1991). When the gene was cloned (Clyne *et al*., 1999a), it was found to encode a POU (Pit-1/Oct-1/Unc-86) domain transcription factor homologous to the vertebrate Brn3 family, whose members are expressed in a variety of sensory neurons (Ryan and Rosenfeld, 1997). Expression of Acj6 was demonstrated in most if not all ORNs, while the mutant phenotype included the loss of

expression of an estimated one-quarter of ORs. At the physiological level, *acj6* mutant sensilla displayed at least three classes of mutant phenotype: (1) loss of olfactory responsivity; (2) transformation to another ORN type, with a different response profile, present in the same sensillum; and (3) transformation to a novel response profile. These phenotypes are consistent with a role for *acj6* in specifying subsets of ORNs; however, the broad expression pattern but more restricted function suggests that it must co-operate with other factors. Clyne *et al.* (1999a) noted that expression could first be observed in the antennal disc at about 16 h APF. Staining at this time is limited to a small number of neurons, which appear (to us) to be products of the wave 1 saccular coeloconic precursors characterized by zur Lage *et al.* (2003). Consequently, Acj6 expression appears not to be in SOPs or presensillum cluster cells, but rather specifically in the ORNs. This relatively late expression suggests that *acj6* must be late-acting and perhaps quite proximal to the choice of OR expression. The first ORN axons reach the AL at 16 h APF, so it is possible that *acj6* could help specify glomerular targets, an interesting avenue for future research.

As the ORNs begin to differentiate and send out axons, they exit the third antennal segment in three well-defined fascicles, pass through the second and first antennal segments, and then fasciculate together. It has been observed in *Drosophila* (Tissot *et al.*, 1997) and in *Bombyx mori* (Svacha, 1992) that the adult nerve appears to follow the path of persistent larval sensory neurons to the antennal lobe. Indeed, this may be a general feature of adult sensory projections (Williams and Shepherd, 2002). Having arrived at the edge of the antennal lobe, the ORN must now synapse (along with other ORNs expressing the same OR) with appropriate partner neurons in the CNS, thereby relaying olfactory information to the brain.

1.12.3.3. Variations

At this point, antennal neurogenesis has been studied rather more extensively in *Drosophila* than in other insects. However, the general periods of antennal neurogenesis can be compared in different insects as follows. In holometabolous insects, neurogenesis in the antennal disc is restricted to relatively short periods in early metamorphosis. Thus, in *Manduca*, neurogenesis occurs during the first two stages (out of 18) of pupal development, and in *Drosophila* between 12 and 22 h APF (in a 100 h period of metamorphosis). This rapid neurogenesis is possible because neurons in the PNS develop in parallel from a large number of precursors (the sensory organ precursors, SOPs) via a small number of divisions (**Figure 7**); this is in stark contrast to the CNS where neurogenesis occurs serially over extended periods from a relatively small number of asymmetrically dividing neuroblasts (Section 1.12.4.2.1 below and **Figure 10**). In hemimetabolous insects, although PNS neurogenesis is presumably mechanistically related to that in holometabolous ones, the lengths of the neurogenic phases are reversed. Peripheral neurogenesis continues throughout nymphal development, while central neurogenesis is restricted to the embryonic phases, at least for the AL neurons (Section 1.12.4.6 below).

The details of sensillar development in other holometabolan antennae are likely to follow the same general plan as in the *Drosophila* antennal disc described in the previous two sections. However, the question of sensillar lineage does remain open. For example, Keil and Steiner (1991) followed the development of olfactory sensilla in the silkmoth, *Antheraea polyphemus*, by electron microscopy studies and concluded that sensilla are monoclonal; the proposed lineages are similar to the basic plan in **Figure 7a**. Whether this monoclonal origin is a definite distinction between Lepidoptera and the very highly diversified Diptera, is an interesting comparative question. Perhaps in the near future it will be possible to compare these developmental events among different species using the molecular findings and tools that have been developed in *Drosophila*.

In *Drosophila*, a rapid and significant increase in our understanding of specification of different ORNs can be expected. One interesting feature is the existence of some spatial order in the antennal disc and, consequently, in the third antennal segment (**Figure 2**). In contrast, there is no obvious distinction among olfactory sensitivity of the 80 or so segments in a *Manduca* antenna (discussed in Tolbert and Sirianni, 1990). In hemimetabolous insects, such as cockroaches, there is successive extension of the antennal flagellum at each nymphal stage, but since the glomerular number is constant from embryogenesis, it would be expected that a diversity of different neurons must be generated at each stage. Another very interesting feature that has come to light in detailed studies of the *Drosophila* antenna, is the specific pairings of ORNs of particular olfactory sensitivities within different sensilla, which suggests a strong coupling between OR choice among ORNs within a sensillum. The authors are not aware of similar physiological studies in other insects, which would indicate if this could be a general phenomenon, but suspect this may well be the case.

1.12.4. Development of the Central Olfactory System: Antennal Lobe

The development of the antennal lobe (AL) and in particular AL glomeruli is one of the major problems in the development of the olfactory system. As the AL is the first sensory relay or processing center in the brain, deciphering its developmental logic is of key importance in understanding how olfactory information is passed to higher centers. The parallel nature of incoming olfactory information, combined with the uniglomerular projection patterns of ORNs and PNs, provides this system with great potential for study of the general problem of wiring specificity in the nervous system. In this section, the development of the major constituents of the holometabolan antennal lobe – ORNs, PNs, and local interneurons (LNs), as well as glia – and how they interact to form the mature structure are discussed.

To appreciate the wiring challenge inherent in the generation of the mature AL, it may be helpful to imagine oneself at the growth cone of a developing ORN. ORNs are generated in the antennal disc and extend axons towards the antennal lobe. As previously described (Section 1.12.2.2.2), ORNs expressing the same receptor must eventually converge on a stereotypically positioned glomerulus within the adult antennal lobe, making connections with projection neuron dendrites and local interneurons. What kind of environment will ORN growth cones encounter as they enter the developing AL and how are they programed to respond to it?

More specifically, from the point of view of wiring specificity, the following questions should be addressed: (1) are ORNs already specified to express a particular OR at the time that their axons reach the AL and if so, how precisely are they specified? (2) is the AL spatially patterned at this time? and (3) are the central partner neurons in the lobe, especially the uniglomerular PNs, already specified to form connections with ORNs bearing a specific receptor? In *Drosophila*, the respective answers to the above questions can be summarized as follows: (1) definitely crudely, probably precisely; (2) yes, but not precisely; and (3) yes, apparently with great precision.

Wiring specificity is probably best considered using molecular genetic approaches, which at present are uniquely available in *Drosophila*. This species will be the focus for much of the discussion, but it is assumed that this logical framework is likely to be generally applicable among other insect species. In particular, glomerular development has been extensively studied from the cellular perspective in *Manduca* and interactions between different cell types have been described and manipulated.

It is important to be quite precise about what is meant by a glomerulus, when it can be said to exist, and how it is experimentally detected. Functionally, a glomerulus represents the convergence of a class of ORNs expressing a particular OR. It constitutes the arrival point of a specific olfactory information channel, and information will be faithfully transferred if PN dendrites that contact these ORNs do not contact other ORNs.

Anatomically, the glomerulus consists of the axon terminals of those ORNs and the processes of partner PNs and LNs, all wrapped by a glial sheath. Experimentally, a glomerulus is usually defined morphologically as an area of increased synaptic density surrounded by an area of reduced synaptic density (presumably the glial sheath or asynaptic neurites).

This typical experimental definition may be somewhat divorced from the functional one. Consider a hypothetical situation in which the glial sheath is removed so that synaptic density is uniform throughout the AL. In this case, glomeruli would not be experimentally discernible by standard techniques, but the antennal lobe would still be highly spatially patterned. While this is clearly hypothetical, during development there may be stages in which synapses do not yet exist between ORNs and PNs and the glial border is poorly developed. ORNs might also have restricted arborizations that spatially overlapped with restricted arborizations of appropriate partner PNs. From the functional perspective, these neurons would be ready to transmit and receive information faithfully, but morphologically this order would not be apparent. Situations like this must be carefully considered before drawing final conclusions from developmental studies.

Finally, it is worth emphasizing that glomerular development may occur in several phases, such as initial formation, maturation, and maintenance. When considering the role of experimental perturbations, developmental time courses are often important to determine which of these steps is affected.

1.12.4.1. Olfactory Receptor Neuron Axons

As described above (Section 1.12.3), in holometabolous insects ORNs are generated in the antennal disc and extend axons towards the brain, typically following the course of the larval antennal nerve. Upon arrival at the AL, it has generally been argued that ORNs are the primary cell type responsible for generating glomerular organization. Results for the model system of choice, *Drosophila*, are first

discussed and then compared and contrasted with work in other insects, especially *M. sexta*.

In *Drosophila*, the development of ORN axons has been followed largely by the use of enhancer trap lines that label subsets of ORNs. This has the advantage of specific and reproducible labeling, but there is the caveat that some populations may be missed. Tissot *et al.* (1997) used two GAL4 lines, KL116 and MT14, which label mostly trichoid and large basiconic sensilla, respectively, to follow in-growth of ORNs into the AL. The ORN axons appeared to reach the lobe around 24 h APF. However, since the trichoid and basiconic sensilla derive from the *amos* dependent third wave of SOPs (described in Section 1.12.3.1 above), it seems likely that there could be some ORNs that reach the lobe sooner than this. Indeed Jhaveri *et al.* (2000b) reported that an *atonal* promoter fusion with the LacZ reporter was expressed in an early population of ORNs, perhaps derived from the *ato* dependent SOPs, which generate coeloconic sensilla; these ORN axons reached the antennal lobe around 18 h APF. Most recently, Jefferis *et al.* (2004) have taken a more unbiased approach to label incoming ORNs using a pan-neural GAL4 in combination with *eyeless*-Flp to drive mitotic recombination in antennal (and eye) disc precursors, generating large, positively marked ORN clones. These results have shown that the first ORN populations reach the antennal lobe around 16–18 h APF (**Figure 8a**).

Having reached the antennal lobe, how do ORNs interact with existing constituents of the AL and what might these be? The development of the other cellular components of the AL will be discussed in detail in the following sections, but there does seem to be a core neuropil that precedes the arrival of ORN axons. In *Drosophila*, this neuropil is strongly immunoreactive for the cell adhesion protein N-Cadherin (Ncad; **Figure 8a**) and consists, at least in part, of the dendrites of PNs (Section 1.12.4.2.2 below; Jefferis *et al.*, 2004). How do ORNs interact with this existing structure? Initially, ORN processes seem to surround the lobe (Jhaveri *et al.*, 2000b; Jefferis *et al.*, 2004) but only enter the core of the AL around 25 h APF (**Figure 8b and c**). Detailed double labeling studies of ORNs and PNs have not yet been carried out, but it may be that at these early stages, ORN axons are interacting amongst themselves rather than with other cell types.

By 30 h APF, there are more axonal processes within the central part of the antennal lobe, and by 36 h APF, at least one glomerulus, VA1, can be identified (Jhaveri *et al.*, 2000b). At 36 h APF, the glomerular organization is rather diffuse – it is clear that while different ORN types are accumulating in distinct foci, they still overlap with their neighbors. A progressive period of refinement follows, with a fairly mature organization observed by 48 h APF (Jhaveri *et al.*, 2000b). It should be recalled that this organization is achieved before the expression of olfactory receptors can be detected (Section 1.12.3.2 above). One key developmental question that remains unanswered is the mode of innervation of individual ORNs. Do they immediately project to a specific region of the lobe in which the future glomeruli will form, or do they initially have

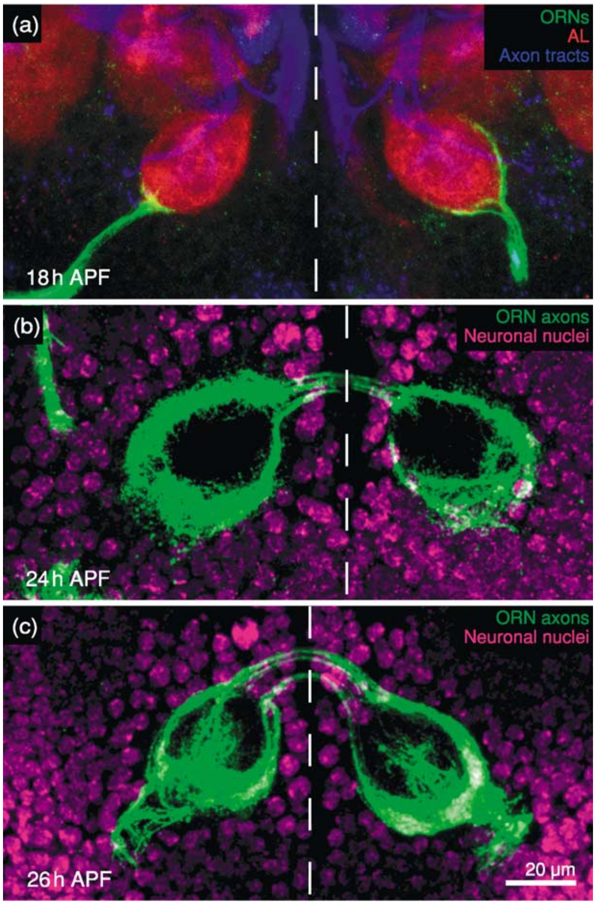

Figure 8 Early development of ORNs in *Drosophila*. The eyless promoter is used to drive mitotic recombination in the antennal disc, generating large GFP-labeled MARCM clones (green) in olfactory receptor neurons. (a) 18 h APF: ORN axons have just reached the antennal lobe (stained by anti Ncad in red) and have started to grow around the margin of the AL. FasII is used to label axon tracts as a counterstain (blue). (b) 24 h APF: ORN axons now form a thick margin around the AL, but do not yet enter the lobe. Counterstain in (b) and (c) is antiembryonic lethal abnormal visual system (Elav), which stains neuronal nuclei (magenta). (c) 26 h APF: ORN axon processes now extend deeper into the antennal lobe. (Reproduced with permission from Jefferis, G.S.X.E., Vyas, R.M., Berdnik, D., Ramaekers, A., Stocker, R.F., *et al.*, **2004**. Developmental Origin of wiring specificity in the olfactory system of *Drosophila*. *Development* 131, 117–130.)

a broad termination area, which is subsequently refined? Enhancer traps that label, from an early stage, ORNs whose axons will target to the same glomerulus should help to address this question.

Molecular genetic studies to understand the basis of axonal targeting to specific glomeruli have only recently begun in *Drosophila*. So far, the axon guidance molecule Dscam (Hummel *et al*., 2003) and the intracellular signaling components Dreadlocks (Dock) and P21-activated kinase (Pak) have been identified as being required for proper ORN axonal targeting (Ang *et al*., 2003). Dscam is a member of the immunoglobulin (Ig) domain superfamily of transmembrane proteins homologous to the human Down's syndrome cell adhesion molecule (apparently so-called largely because of its location on chromosome 21 rather than any clear functional link to the Down's syndrome). When the *Drosophila* gene was first cloned and shown to be required for axon guidance in the larval visual system, it aroused considerable interest because of its potential to encode a huge number of isoforms, an estimated 38 016, by alternative splicing, largely in the extracellular region containing the Ig domains (Schmucker *et al*., 2000). Hummel *et al*. (2003) find that ORNs and central neurons within the AL express multiple isoforms of Dscam. By making large clones of mutant *Dscam*$^{-/-}$ ORNs, it seems that Dscam is required for correct targeting of some but not all ORNs; mutant neurons converged at ectopic locations within, or occasionally outside, the antennal lobe. Interestingly, mutant maxillary palp ORNs sometimes formed several sites of convergence completely outside the AL in the subesophageal ganglion, which is, for example, a normal site of convergence for gustatory neurons. These ectopic structures had the appearance of glomeruli (by neuropil staining), and different ORN classes still seemed to segregate into different foci, suggesting that Dscam is required for guidance, or perhaps growth, but is not (uniquely) required for different ORN classes to segregate in a class-specific manner. Additional studies will be required to determine what role Dscam diversity may play in the development of different ORN classes.

In a second study, Ang *et al*. (2003) used a similar methodology to investigate the function in ORNs of Pak and Dock, a protein kinase and an adaptor protein, respectively, both previously shown to be required for downstream signaling from receptors involved in photoreceptor axon guidance (Garrity *et al*., 1996; Hing *et al*., 1999) and perhaps Dscam signaling (Schmucker *et al*., 2000). Whole animal mutants or animals with large clones of mutant ORNs (but wild-type target neurons), had antennal lobes which were significantly reduced in size and showed little glomerular organization; *pak* and *dock* function seemed to be specifically required in the ORNs since expression of recombinant wild-type Pak or Dock in ORNs rescued the phenotype of whole animal mutants. Although these genes are clearly required for ORN targeting, the phenotypes did not show any specificity for particular ORN subtypes.

Although *Dscam* mutants did show some subtype specificity, the question of what molecular mechanisms endow different ORNs with different target specificities remains very much open. In this regard, recent work in *M. sexta*, describing the expression pattern of the cell adhesion molecule FasII (Higgins *et al*., 2002) and an Ephrin (Eph) and its receptor (Kaneko and Nighorn, 2003), is most intriguing. These molecules are expressed in ORNs during glomerular formation and seem to be differentially expressed in ORNs targeting to different glomeruli (**Figure 9**). Most interestingly, Ephrins, which are usually repulsive cues, and their receptors show a complementary expression: cells expressing a high level of the receptor express a low level of the ligand. This suggests that they may be involved in axo-axonal signaling during segregation of different ORN classes into different glomeruli (Kaneko and Nighorn, 2003).

1.12.4.2. Projection Neuron Dendrites

1.12.4.2.1. Neurogenesis In *Drosophila*, Projection neurons (PNs) of the adult AL are generated during both the embryonic (G.S.X.E. Jefferis, E.C. Marin and L. Luo, unpublished data) and larval phases (Stocker *et al*., 1997; Jefferis *et al*., 2001) and must, therefore, be essentially complete before the generation of ORNs in the antennal disc, which begins around 12 h APF (see Section 1.12.3.1 above). Their generation pattern is believed to conform to the general model of neurogenesis in the *Drosophila* CNS: a neuroblast divides asymmetrically to regenerate a neuroblast along with a smaller ganglion mother cell (GMC), which divides once more to make two postmitotic neurons (**Figure 10**).

The neurogenesis of different classes of PN has been studied in detail using the *GAL4-GH146* enhancer trap line (Stocker *et al*., 1997) and the mosaic analysis with a repressible cell marker (MARCM) system for mosaic analysis (Lee and Luo, 1999; review: Lee and Luo, 2001). MARCM allows for positive labeling of a small fraction of cells using a membrane targeted GFP, in an otherwise unlabeled brain. Specific cell populations are targeted by the combination of tissue specific GAL4 enhancer trap lines and the application of a heat

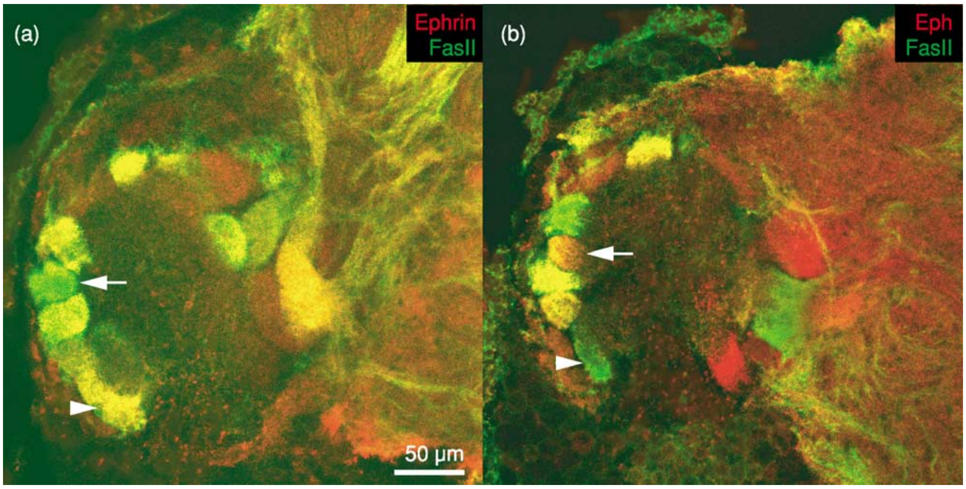

Figure 9 Mosaic expression of FasII and Ephrin/Eph receptor in *Manduca* ORNs. Frontal section through a *M. sexta* antennal lobe, with the antennal nerve entering from the right (lateral) and dorsal uppermost in the images. Samples have been double labeled at pupal stage 6 for FasII (in green) and Ephrin (in (a)) or Eph receptor (in (b)) (in red). Note the mosaic expression of these three molecules in different glomeruli. Comparison of indentifiable glomeruli suggests that ORNs expressing high levels of the repulsive Ephrin ligand tend to express low levels of the Eph receptor and vice versa (compare glomeruli identified by arrowheads or arrows, respectively). Other evidence suggests that Ephrin and Eph receptors are both expressed on ORN axons, but not on PN dendrites. (Reproduced with permission from Kaneko, M., Nighorn, A., **2003**. Inter-axonal Eph-ephrin signaling may mediate sorting of olfactory sensory axons in *Manduca sexta*. *J. Neurosci. 23*, 11523–11538; © by the society for Neuroscience.)

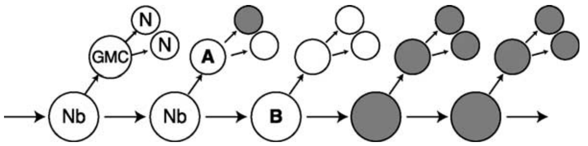

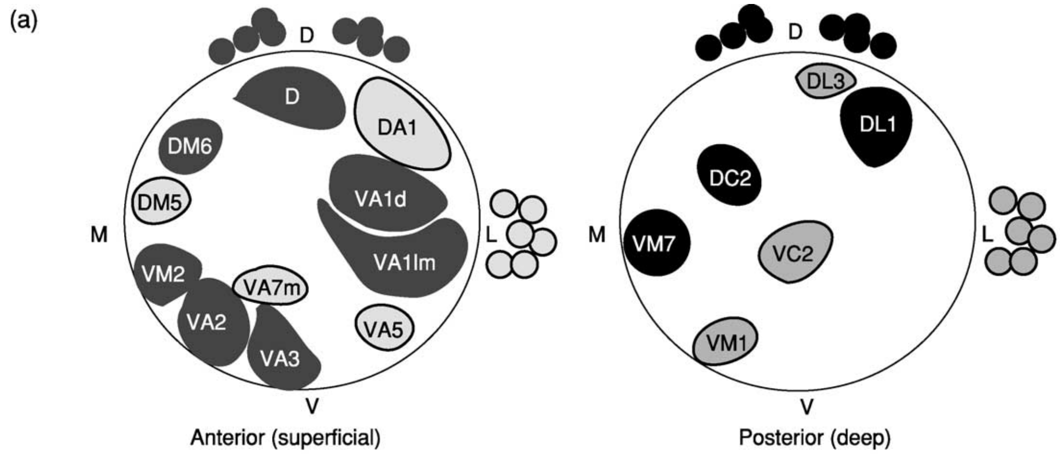

Figure 10 CNS neuroblast division pattern in *Drosophila*. In the CNS, neurons are generated by the asymmetric division of a neuroblast (Nb). At each division, the Nb divides asymmetrically to regenerate a Nb, while generating a smaller ganglion mother cell (GMC). This GMC divides once more to generate two postmitotic neurons (N). If a clonal analysis system such as MARCM is used to investigate neurogenesis, this pattern of division results in the generation of characteristic clonal units. If a clone is generated at point A, then a single labeled cell will be generated (filled gray circles). In contrast, if the clone is generated by an event at point B, then 50% of the time the Nb itself falls within the clone and all subsequent daughter cells will be labeled. Another 50% of the time the GMC falls within the clone resulting in a labeled two-cell clone (not shown).

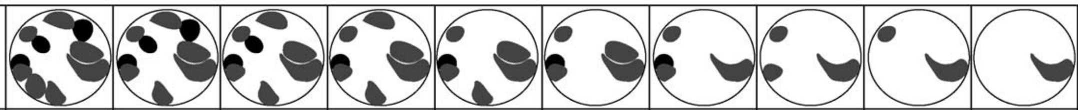
shock pulse at a desired time in development; the heat shock drives mitotic recombination, which causes permanent labeling of a fraction of the cells dividing at that time and any progeny they may subsequently generate. Given the asymmetric division pattern of CNS neuroblasts described above (Figure 10), MARCM typically generates three kinds of labeled clones: (1) single cells (when a recombination event occurred in a dividing GMC); and, if recombination occurs in the neuroblast, either a labeled (2) two-cell or (3) a neuroblast clone, in which all of the subsequent progeny of the neuroblast fall within the clone.



GH146 labels approximately 90 PNs, which are divided into three discrete clusters of cell bodies, positioned anterodorsal (ad), lateral (l), and ventral (v) to the antennal lobe (Stocker *et al.*, 1997; Jefferis *et al.*, 2001), with approximately 50, 35, and 6 cells in each cluster according to Jefferis *et al.* (2001). Application of the MARCM method demonstrated that these three groups of cells were born from three different identifiable neuroblasts (Nbs). While the lateral and ventral clusters seemed to consist entirely of neurons born during postembryonic development, this seems to be the case for only about 30 of the 50 adNb neurons (Jefferis *et al.*, 2001). The balance, about 20 neurons, seem to be generated by the same neuroblast during embryonic development and, therefore, to function both during larval and adult life in their respective olfactory systems (G.S.X.E. Jefferis, E.C. Marin, and L. Luo, unpublished data). An earlier study suggests that the lateral group of PNs may be produced by a single neuroblast, which divides unusually early in larval development (Stocker *et al.*, 1997); although this neuroblast may be dividing in newly hatched larvae and probably also in emrbryos, it does not seem to produce GH146 positive PNs until 24 h after larval hatching (Jefferis *et al.*, 2001).

Does any logic connect a PN's parental neuroblast and its connectivity? The adNb and lNb PNs were for the most part uniglomerular and projected axons via the inner iACT to the MB calyx and LH; vNb PNs all projected via the mACT and while some were uniglomerular, one striking example

Figure 11 Lineage and birth order predict dendritic targets of *Drosophila* PNs. (a) Stereotypic dendritic projection patterns of 2 PN lineages superimposed on cartoons of sections through the anterior and posterior antennal lobe. PNs of the anterodorsal (darker cell bodies and glomeruli) and lateral (paler cell bodies and glomeruli) lineages send their dendrites to stereotyped, intercalated but nonoverlapping glomerular targets. This indicates that the connections that any particular PN can make are limited by its parental neuroblast. D, V, L, and M indicate the dorsal, ventral, lateral, and medial aspects of the lobe, respectively. Individual glomeruli are named according to the map of Laissue *et al.* (1999). (b) Analysis of Nb clones indicates that the last-born PNs of the anterodorsal lineage will always go on to innervate a specific glomerulus, VA1lm. Neuroblast clones generated a little earlier in development have PNs, whose dendrites innervate both VA1lm and a second glomerulus DM6. Neuroblast clones are generated a little earlier yet, contain PNs innervating VA1lm, DM6, and VM2. In this manner it was possible to work all the way back to the large clones generated after larval hatching with each clone type completely containing the smaller clones that follow it. The conclusion from these observations is that PNs innervating different glomeruli must be generated in a highly stereotyped order. ((a,b): Reproduced with permission from Jefferis, G.S.X.E., Marin, E.C., Stocker, R.F., Luo, L., **2001**. Target neuron prespecification in the olfactory map of *Drosophila*. *Nature 414*, 204–208; © Nature Publishing Group.)

innervated almost all the glomeruli in the lobe (see Section 1.12.2.2.3 above for an anatomical summary). Therefore, it seems that different functional types of PN are produced by different Nbs. What other organizational features exist? One interesting feature of this initial analysis was that PNs born from the three Nbs had highly distinctive and reproducible dendritic innervation patterns in the lobe. Furthermore, the major groups, the anterodorsal and lateral lineages, innervated intercalated but nonoverlapping sets of glomeruli (**Figure 11a**). Thus, the daughter PNs of the adNb and lNb are restricted to forming dendritic connections with discrete sets of incoming ORNs expressing different sets of ORs and, therefore, different olfactory information (Jefferis *et al.*, 2001).

Are the individual PNs within a lineage further restricted in their dendritic connectivity? Apparently, yes. Analysis of single cell MARCM clones of the adNb, at different times in larval development, produced an ordered but overlapping set of birth times for PNs innervating different glomeruli. All single cell clones generated during the first 24 h of larval development had dendrites that innervated the DL1 glomerulus in the mature antennal lobe. For technical reasons, the accuracy of birth dating by the

MARCM system in this experiment was probably only about ±12 h by the end of larval development, so a second analysis was carried out. Neuroblast clones of the anterodorsal Nb generated at different times in development were analyzed. As expected, later-born neuroblast clones had fewer cells and innervated correspondingly fewer glomeruli than the larger clones generated earlier in development. However, intriguingly, the last 3–5 cells of the adNb lineage all innervated the same glomerulus, VA1lm. Furthermore, clones generated slightly earlier in development innervated this glomerulus (VA11m) and a second glomerulus, DM6. All 54 clones analyzed from a variety of developmental time-points confirmed this impression of a fixed sequence: each smaller and later-born clone was completely contained within the earlier born clones that preceded it (**Figure 11b**). In short, for the adNb at least, PNs are born in a highly stereotyped order. Since PN axonal and dendritic projection patterns are tightly coupled (as described in Section 1.12.2.2.5 above), this means that PNs pick up and deliver olfactory information in a highly stereotyped fashion according to birth order (Jefferis *et al*., 2001).

How can the birth order of a PN influence its dendritic and axonal connectivity? In the case of DL1 PNs (**Figure 11**), connections are formed as much as 5 days after birth. One possibility is that PN dendrites might differentiate sequentially according to their birth order; if different classes of ORNs also arrived sequentially at the antennal lobe, then sequential differentiation could explain class specific ORN/PN connections. However, Jefferis *et al*. (2001) reported that PNs born at different times in development have similar dendritic arborizations at the time of ORN ingrowth, making such a sequential differentiation hypothesis most unlikely. Instead, it seems that PNs are likely to possess molecular differences, which allow class specific interactions with incoming ORN axons.

How could a neuroblast generate a series of molecularly distinct PNs? One possibility is that time-varying extrinsic signals, present at or about the time of PN birth, could cause PNs to adopt different fates. A second possibility is that sequential signaling among PNs, after their birth, could lead to a coordinated set of fates. A final possibility, which the present authors favor, is that PNs generated at different epochs of neuroblast division may inherit molecular determinants that direct a distinct set of fates. This possibility is supported by the demonstration, in neuroblasts of the *Drosophila* embryo (both *in vivo* and in culture), of the cyclic expression of a set of transcription factors (review: Brody and Odenwald, 2002) and, in particular, the demonstration that these factors directly regulate the fate of GMCs/neurons born at different times (Isshiki *et al*., 2001).

In conclusion, it seems that in *Drosophila*, second order projection neurons are precisely specified to form connections with specific incoming sensory neurons, and relay that information to higher olfactory centers. It is not yet clear whether this is a general phenomenon in insect (or vertebrate) olfactory systems. However, this stereotypical wiring may be a substrate for stereotypical and innate behavioral responses to odors, which are a general feature of insects.

1.12.4.2.2. Morphogenesis In the section above, the generation of different classes of PNs in *Drosophila* have been discussed. How do these classes of PNs acquire their distinctive shape and connectivity? These issues are addressed here, first by detailing the development of PNs and then by highlighting some recent genetic studies. While there is a strong recent literature on PN development in *Drosophila*, development of PNs has also been described in other insect species including *Manduca* (Malun *et al*., 1994), which will be discussed in Section 1.12.4.5.

Developmental studies of the AL, and specifically of PNs, in *Drosophila* are a relatively recent phenomenon, but there has been good progress. In their initial characterization of the GH146 enhancer trap line, Stocker *et al*. (1997) noted that GH146-positive PNs showed signs of dendritic outgrowth at 24 h APF, shortly after the arrival of ORN axons. By 48 h APF, dendrites appeared to adopt a glomerular organization. A second study by Jhaveri and Rodrigues (2002), focused mainly on the development of ORNs, but also presented interesting results on PN development. In particular, they observed that GH146-positive PNs had dendritic arborizations in the area of the developing antennal lobe as early as 14 h APF. However, since GH146 labels both larval and adult PNs (see Section 1.12.4.2.1 above), it is not possible to conclude whether these dendrites are the remnants of the larval antennal lobe or newly developing dendrites of the adult antennal lobe. Jhaveri *et al*. (2002) also demonstrated that at 45 h APF, PNs seemed to have a glomerular organization, confirming the observation of Stocker *et al*. (1997). A more recent study by Jefferis *et al*. (2004) significantly extends these findings. The MARCM system was used to follow identified PNs with single cell resolution. Additionally, by labeling cells born at or after defined periods in development, it was possible to tease apart contributions from the degenerating larval lobe and the newly developing adult antennal lobe.

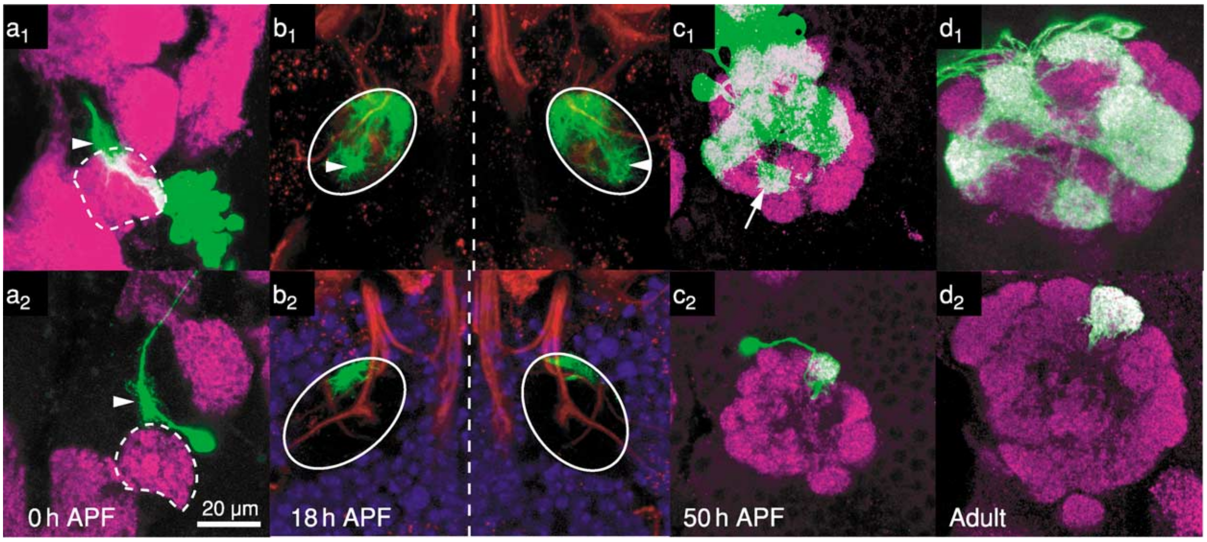

Figure 12 Development of *Drosophila* PNs. Anterodorsal neuroblast (a_1–d_1) or single cell (a_2–d_2) MARCM clones of projection neurons at different developmental stages: 0, 18, 50 h after puparium formation and adult (a, b, c and d, respectively). Counterstains are monoclonal antibody nc82 (magenta) which recognizes neuropil, FasII (red) for axon tracts, and Elav (blue) for neuronal nuclei. (a) Dotted outlines indicate larval antennal lobe, arrowheads developing PN dendrites. PN dendrites grow out from axonal processes in a location adjacent to the larval lobe; the overlap between green dendrites and magenta neuropil in (a_1) is an artifact of the maximum intensity Z projection of a stack of confocal images. (b) Solid lines delineate the adult antennal lobe, while a dotted line indicates the midline; two arrowheads indicate dendritic arborizations in similar areas of the developing antennal lobe. Note how the two single-cell clones in (b_2) (which will occupy a specific glomerulus, DL1) occupy similar regions of the developing AL. (c) Glomeruli can be detected by the neuropil marker nc82 by 50 h APF. Single cell and neuroblast clones indicate that PNs have dendritic arbors confined to appropriate and identifiable glomeruli. (d) There is continued growth of the AL during the second half of pupal development. (Reproduced with permission from Jefferis, G.S.X.E., Vyas, R.M., Berdnik, D., Ramaekers, A., Stocker, R.F., *et al.*, **2004**. Developmental origin of wiring specificity in the olfactory system of *Drosophila*. *Development 131*, 117–130.)

The first finding of this new study was that at 0 h APF, PN dendrites begin to elaborate new dendrites at a location adjacent to, but distinct from the larval lobe (**Figure 12a**). However, earlier studies had argued that the larval antennal lobe is the direct precursor of the adult antennal lobe (e.g., Stocker *et al.*, 1995); the discrepancy is probably due to the fact that these structures are small, directly adjacent, and hard to distinguish without the molecular markers now available. It will be interesting to determine if other holometabolous insects show any separation of the two structures.

The next critical point of this study (Jefferis *et al.*, 2004) was an analysis of PN dendrites at 18 h APF. As described in Section 1.12.4.1 above, ORNs first reach the antennal lobe around 16–18 h APF, and remain at the periphery of the lobe for some time thereafter. However, at this stage, PN dendrites have extended throughout the developing antennal lobe (**Figure 12b$_1$**). Most importantly, PN dendrites at this time occupied spatially stereotyped locations within the lobe. For example, early born PNs that innervate the DL1 glomerulus already had dendritic arborizations restricted to a dorsolateral corner of the developing antennal lobe (**Figure 12b$_2$**). Although PN dendrites of different classes still showed some overlap at these stages, this observation suggests that PNs are able to generate a coarse dendritic map in the absence of their presynaptic ORN partners. The implications of this early ORN independent phase of development are discussed below (Section 1.12.4.5).

Development proceeds rapidly after ORN arrival, so that glomeruli appear morphologically almost mature by 50 h APF, as determined either by PN dendrite projection patterns or by the monoclonal antibody nc82, which detects neuropil areas (**Figure 12c**; Jefferis *et al.*, 2004). Although organizationally mature, at this stage ALs are still at least 50% smaller in linear dimensions (and therefore about a quarter of the volume) than in the adult (**Figure 12d**). It is not clear whether this growth represents predominantly local increases in the arborization of the existing axons and dendrites or the ingrowth of new processes, such as local interneuron neurites or glial processes (see below).

The developmental studies described above will provide an important basis for understanding the work that is now underway in a number of laboratories into the genetic basis of wiring specificity in

the antennal lobe of *Drosophila*. The first foray into the genetics of this system was reported by Komiyama *et al.* (2003). A candidate gene approach identified two POU domain transcription factors, abnormal chemosensory jump 6 (Acj6, previously mentioned in Section 1.12.3.2 in the context of ORN differentiation) and Drifter (Dfr) expressed in the anterodorsal and lateral PN lineages, respectively. Loss-of-function analysis, using the MARCM system to generate homozygous mutant clones in heterozygous brains, indicated that each gene is required for correct dendritic targeting of a subset of PNs in their respective lineages. Furthermore, reciprocal misexpression experiments (of Acj6 in the lateral lineage or Dfr in the anterodorsal lineage) caused dendrites to target inappropriate glomeruli, including glomeruli usually targeted by the opposite lineage. However, neither Acj6 nor Dfr misexpression generated a complete switch of dendritic targeting, even when the misexpression was coupled with removal of the endogenous transcription factor. The conclusion was that *acj6* and *dfr* are probably part of a transcriptional program, which generates discrete PN fates in different neuroblast lineages, perhaps in combination with the ubiquitous neuroblast transcriptional timer mechanism hypothesized above (Section 1.12.4.2.1). Finally, it should be noted that *acj6* mutant PNs also had axonal targeting defects, which are discussed below (Section 1.12.5.1).

1.12.4.3. Local Interneurons

Compared to the recent accumulation of information on ORNs and PNs, little is known in *Drosophila* about the development of local interneurons (LNs). Stocker *et al.* (1997) followed the expression of an enhancer trap GH298, which labels about 20 multiglomerular LNs; they first observed detectable expression at about 48 h APF and, then, in only about 10 cell bodies. Whether this represents late differentiation of LNs or simply late expression of this marker is unclear. Finer developmental time courses and additional enhancer trap lines will probably soon resolve this issue.

A little more information about the development of LNs is available in *M. sexta*. Antennal lobe development in *Manduca* is characterized by a clear distinction between two neuropil layers. A central core of the AL initially contains the processes of central neurons such as PNs and LNs. When ORN axons arrive, they are restricted to a superficial layer surrounding the antennal lobe, and it is in this layer that protoglomerular accumulations form. Although LNs, as detected either by single cell fills (Oland *et al.*, 1990) or by GABA immunoreactivity (Homberg and Hildebrand, 1994), have already arborized extensively by the time ORNs arrive, they initially remain restricted to the core neuropil, and only later invade the protoglomerular layer several days after the formation of contacts between ORNs and PNs.

Stocker *et al.* (1997) also used hydroxyurea treatment at different times in development to ablate dividing neuroblasts. As mentioned in Section 1.12.4.2.1, an early-dividing lateral neuroblast seems to generate lateral PNs. Since early larval application of hydroxyurea also prevented formation of LNs, the authors suggested that the same neuroblast may generate LNs and the lateral group of PNs. A more direct test, for example, clonal analysis using drivers expressed in both PNs and LNs, will be required to confirm this suggestion.

The authors are not aware of any developmental data concerning non-GABAergic LNs in *Drosophila*. However, a serotonergic neuron has been identified in a number of insect species including *M. sexta*, in which it seems to be born embryonically, or at an early larval stage, and persist right through pupal development into the adult (Kent *et al.*, 1987). A detailed developmental study suggests that these neurons show a similar developmental pattern to the GABAergic PNs described above (Oland *et al.*, 1995), i.e., early arborization within the central core, followed by later invasion of the protoglomerular layer.

1.12.4.4. Glia

As described in Section 1.12.2.2.2 above, glial processes wrap individual glomeruli (although the extent of the glial sheath differs markedly among insects) and separate the AL from other neuropil compartments. In *Drosophila*, glia seem less likely to play a significant role in glomerular development, since their processes only invade the AL around 48 h APF, when glomerular organization is largely mature (Jhaveri *et al.*, 2000b; Jefferis *et al.*, 2004). However, there is a ring of glial cell bodies surrounding the lobe, and these cells could provide an external cue, which might be of significance, for example, when ORNs first invade the periphery of the antennal lobe (see Section 1.12.4.1 above). Additional glia are generated after ORN arrival (Jhaveri *et al.*, 2000b), although it is not clear if gliogenesis is dependent on ORNs.

Work in *Manduca* has highlighted a significant role for glia in glomerular development. Before ORN arrival, glia form a border around the AL, which is several cell bodies thick. At pupal stage 4, when ORNs first enter the AL, glial cell processes start to extend into the lobe, and further glial proliferation begins (Oland and Tolbert, 1987). The

changes in glial cell structure (but not number, which is hormonally regulated; Kirschenbaum *et al.*, 1995) are dependent on ORN axon arrival, since they do not occur in deantennated lobes (Oland and Tolbert, 1987). In developmental stages 5 and 6, ORN axons coalesce into protoglomeruli, which are then rapidly invaded by PN dendrites; as this occurs, glial cell bodies migrate and processes extend further, partitioning off the newly forming glomeruli. Glia appear to be actively involved in this process of glomerular maturation, since γ-irradiation (Oland *et al.*, 1988) or hydroxyurea (Oland and Tolbert, 1988) treatment at stages 4 and 5 (after antennal and central neurogenesis are complete) prevents the normal large expansion in glial number and seems, consequently, to perturb glomerular development. Protoglomerular accumulations of ORNs dissolve rapidly in these glial deficient conditions, except in occasional locations, where there are enough glia to form a crude septa (Baumann *et al.*, 1996); there is also a consequent absence of LN dendritic tufts.

Do glia have a very specific scaffolding role during glomerular formation or are they additionally required for ORN targeting to the correct region of the AL? It would be rather interesting to know if the diffuse ORN terminations that persist after manipulations to prevent the normal expansion of glial populations show signs of spatial patterning; the ability to label ORN classes in *Manduca* might permit such an experiment.

Why should glia have a vital scaffolding role during glomerular formation in *Manduca*, while in *Drosophila* glial cell processes only invade the AL when glomerular formation is largely complete? One viable hypothesis might be the effect of glomerular size, which is much larger in *M. sexta*, where a typical glomerulus developing at stage 5/6 can vary from 20 to as much as 50 μm in diameter; 50 μm is about the size of the whole AL in *Drosophila* at 48 h APF, when glomerular organization is essentially complete. To give a numerical comparison, approximately 5000 ORNs terminate in a mature *Manduca* glomerulus versus an average of about 25 in *Drosophila*. Perhaps, the accumulation of a much larger number of ORN terminals in a *Manduca* protoglomerulus requires an additional support structure, in addition to adhesive interactions among axons.

Besides their role in protoglomerular stabilization, a second function for glia has been proposed in *Manduca*. Oland *et al.* (1998) have demonstrated that ORN axons show a dramatic reorganization at the point of entry into the antennal lobe, and identified a substantial glial population in this region. In this sorting zone, axons appear to defasciculate and selectively refasciculate with other ORNs, which then target to the same glomerulus. Rössler *et al.* (1999a) find that the generation of the glial sorting zone depends on central gliogenesis, which appears to be induced by ORN axons (in contrast to proliferation of the AL neuropil associated glia described above), and that in its absence (using γ-irradiation as above), selective refasciculation is disrupted and ORNs frequently overshoot the lobe completely.

1.12.4.5. Cellular Interactions in AL Development

Neuronal processes of sensory and central neurons must interact to form mature glomeruli. Exactly when and where this occurs and the significance of, for example, ORN–ORN interactions versus ORN–PN interactions, all remain important questions. In *Drosophila*, the developmental studies described above (Sections 1.12.4.1 and 1.12.4.2.2) suggest that PN patterning occurs early, that ORNs initially remain restricted to the exterior of the lobe, and that glia are relatively late participants in AL development. This has led Jefferis *et al.* (2004) to hypothesize that both PNs and ORNs may have substantial autonomous patterning ability. Generation of the final mature organization of the antennal lobe would result from the interaction of these two spatial maps. Initial coarse targeting by both populations could explain how specific sets of ORNs and PNs are able to find each other in the complex environment of the developing antennal lobe.

What cellular cues might be required for these initial ORN and PN targeting steps and subsequent glomerular formation? The logic of highly specific wiring of ORNs and PNs has been uniquely demonstrated in *Drosophila*, but experiments to address the significance of interactions between different cell types in AL development have been much more extensive in other systems. In particular, a lot of work has been done in *Manduca*, where surgical manipulations including deantennation, antennal disc transplantation, and ablation of certain PN populations, have proved possible, in addition to the glial ablation studies described above.

1.12.4.5.1. Influence of ORNs on AL development Antennal denervation before ORN ingrowth results in a failure of glomerular organization, although an AL of reduced size still forms (Hildebrand *et al.*, 1979). There seems to be a threshold effect: partial removal of the developing antenna indicates that if 12 or more of the normal 80 antennal segments form, then glomerular development will proceed relatively normally. The lobe will, of course, be much smaller, given that the ORN

number is much reduced from about 300 000 to, for example, 20 000 per antenna, when 12 antennal segments remain (Tolbert and Sirianni, 1990). Around this threshold, about two-thirds of the normal number of glomeruli form. When 30 antennal segments remained, essentially all glomeruli formed (Tolbert and Sirianni, 1990).

Similar deantennation experiments have been carried out in a wide variety of insects including *Periplaneta* (Salecker and Boeckh, 1996) and *Apis* (Gascuel and Masson, 1991), with each case reporting a loss of glomerular organization. Surgery of this type would be extremely difficult in *Drosophila*, but examination of mutants of the gene *lozenge* (*lz*) provides some comparison: lz^3 mutant antennae lack all basiconic sensilla and there is a loss of the glomerulus V, a major basiconic target, apparently because of a requirement for *lz* in the antenna (Stocker and Gendre, 1988). It would appear, therefore, that ORNs are strictly required for the formation of olfactory glomeruli. There also seems to be a requirement for maturation: ORNs reach the *Manduca* AL at stage 3, glomeruli are evident by late stage 5, but deantennation until stage 7 can cause a significant regression in glomerular organization, suggesting that ORN contact is required for at least 4–6 days (Tolbert and Sirianni, 1990). Salecker and Boeckh (1996) report a similar phenomenon in *Periplaneta*.

Glomerular organization is only one end point in the development of the AL; as discussed in the introduction to Section 1.12.4, spatial patterning may exist in the absence of morphologically discernible glomeruli. The consequence of deantennation on PN development was studied in *Manduca* by Malun *et al.* (1994), who found that PNs nevertheless extend dendrites into the outer regions of the lobe. At stages 5 and 6 when glomeruli would normally be forming, PN arbors appear broader and more diffuse, but they do form a glomerular termination, apparently analogous to a single early forming glomerulus at the entry to the AL. Even at the last pupal stage (18), single-filled PNs had sparser dendritic arbors than normal, but innervated a discrete portion of the AL, not substantially different in size from a normal glomerulus. These results suggest that, at least in *Manduca*, PN dendritic development, while clearly influenced by ORNs, is less dependent on ORNs than might have been expected. It is also interesting to note that PN dendritic arbors can be maintained without ORN partners. Perhaps this stabilization is due to contact with other neurons in the AL or with glia. Similar experiments have yet to be reported in other species, with the exception of Salecker and Boeckh (1996), who reported that mass stained PNs in *Periplaneta* seem to be more severely affected by deantennation. Dendritic arborizations were severely reduced and disorganized when deantennated embryos were examined at late embryonic stages (16 days after surgery). It would be interesting to know, in this case, whether PN dendritic arborizations ever form (i.e., a potential requirement for maintenance rather than elaboration), and whether single cell labeling studies might reveal any remaining signs of order.

1.12.4.5.2. Influence of ORNs on sexually dimorphic glomeruli If ORNs are necessary for glomerular formation, to what extent can they be considered sufficient? The sexually dimorphic glomeruli of *Manduca* have provided an interesting test case. In a classic experiment, Schneiderman *et al.* (1982) developed a surgical technique to transplant the larval antenna and its attached antennal disc. When a male antennal disc was grafted into a female host before pupariation, the resultant male ORNs were able to induce the male specific MGC in the otherwise female brain. In contrast, when a female disc was transplanted into a male host, no MGC developed. Rössler *et al.* (1999b) recently revisited this experiment. They were able to confirm the presence in 18/21 cases of all three MGC glomeruli, the cumulus and the two toroids. Indeed, in some gynandromorphs, the induced MGC was morphologically indistinguishable from the wild-type. In the case of female transplants into male hosts, Rössler *et al.* (1999b) were also able to demonstrate the induction of what appear to be the two lateral female specific glomeruli (LFGs).

How are postsynaptic PNs influenced by transplanted ORNs? While the cell number in the medial cluster of PN cell bodies is sexually dimorphic, with an additional 30 cells in males (Homberg *et al.*, 1988), this is not under afferent control, since no change in PN cell number was observed in either class of gynandromorph (Rössler *et al.*, 1999b). In contrast, female PNs of the medial cluster do innervate ectopic MGC glomeruli (Rössler *et al.*, 1999b). This raises a very interesting question: to what extent can the ectopic ORNs specify central connectivity of their partner neurons?

A follow-up to the original Schneiderman experiment had shown that some female moths with transplanted male antennae could show male-like behavior in response to female pheromone (Schneiderman *et al.*, 1986). It might be revealing to trace out the axonal projection pattern of PNs in gynandromorphs, and see whether their connectivity is characteristic of host sex or antennal sex. It is

interesting to note in this context that the Rössler *et al*. (1999b) study suggests that the PNs innervating the MGC and the LFGs may be to a certain extent homologous. In both males and females, these PNs develop particularly early. Furthermore, in the case of female into male grafts, the LFGs were very strongly innervated, perhaps by the extra 30 male specific PNs, while in male into female grafts, the MGC was comparatively weakly innervated. Perhaps MGC and LFG PNs have a rather similar dendritic branching specificity – the heterotypic transplant may "work," in part because of the existence of a molecularly similar postsynaptic population, in addition to any instructive ability of ectopic ORNs. Homology of sexually dimorphic glomeruli has also been proposed by Rospars and Hildebrand (2000) in a recent high-resolution study of the structure of the *M. sexta* AL; a third female specific glomerulus was identified, and the group of three female specific glomeruli were proposed to be directly homologous to the three MGC glomeruli.

1.12.4.5.3. Influence of PNs on AL development As discussed above, ORNs seem to be strictly required for glomerular formation, although perhaps not for dendritic arborization. What role then do projection neurons PNs play in the development of other cell types? The only significant attempt to address this question so far has been in *Manduca*. In a rather impressive feat of surgery, Oland and Tolbert (1998) were able to excise a large fraction, or in some cases all, of the PNs in the medial cell cluster, which may be composed exclusively of PNs (Homberg *et al*., 1988). Even in the case in which no medial PNs could be detected, glomerular development, in the region normally innervated by these PNs, appeared largely unaffected. In particular, ORN axons still formed protoglomeruli and proceeded to a mature glomerular organization. Although it is possible that PNs derived from the second major cluster (lateral) could substitute for medial PNs in these circumstances, Oland and Tolbert (1998) argued that they would arrive later in development, after ORN arrival. Therefore, from these experiments, it would seem that PN dendrites are unlikely to act as targets for incoming ORN axons, or provide a scaffold for other central neuron dendrites.

The experiments described above suggest that PNs may not be required for the development of other cell types in the AL. However, PNs may interact with each other during development. In *Drosophila*, PN dendrites are substantially patterned at 18 h APF and appear to be the major component of the developing antennal lobe, up until this point. This suggests that dendro-dendritic interactions among PNs may play a role in patterning of the AL (Jefferis *et al*., 2004). Experimental evidence to support this comes from studies on the role of the cell adhesion protein N-cadherin in PN development (Zhu and Luo, 2004). Single-cell MARCM clones revealed that PNs homozygous for a loss-of-function *N-cadherin* mutation no longer restrict their dendrites to single glomeruli. Interestingly, labeled wild-type single PNs, in the presence of unlabeled neuroblast clones homozygous for the *N-cadherin* mutation, exhibit these same dendritic overspilling phenotypes. This indicates that the PN–PN interaction mediated by N-cadherin is essential for limiting dendritic targeting of each PN to a single glomerulus.

1.12.4.6. Development of the Hemimetabolan AL

The sections above have focused on *Drosophila* and *M. sexta*, both holometabolous insects. How does the development of hemimetabolous insects compare? In general, one would expect that by the end of embryonic development, the hemimetabolan AL would be functionally almost equivalent to the adult; sexually dimorphic functions might be a possible exception to this rule. However, the size and innervation of the antennal lobe must be very different at these two stages. At each new molt, new antennal segments are added (Rospars, 1988), so that OR number in *Periplaneta* increases from 14 000 at the first larval molt (Schaller, 1978) to more than 200 000 in the mature adult (Section 1.12.2.3.3). The glomeruli, however, do not increase in number. For example, in *Blaberus craniifer*, 109 glomeruli can be counted at all larval stages to adulthood (Rospars, 1988). While the ORN number clearly increases greatly, neurogenesis of antennal lobe neurons seems to occur solely during embryogenesis, suggesting that the number of PNs leaving the antennal lobe is likely to be fixed. This is in contrast to the MBs, where, for example, in *Periplaneta*, neurogenesis continues through successive nymphal stages leading to a massive increase in MB neuron number, paralleling the increase in ORNs (see Section 1.12.5.4.1 below).

Among hemimetabolous insects, the most detailed work on the initial development of the antennal lobe glomeruli has been reported in *Periplaneta* (Salecker and Boeckh, 1995). The sequence of events during the 31 days of embryonic development can be described as follows. At stage E6, neurogenesis is evident in the deuterocerebrum, and there are already signs of a fine neuropil. By E10, the neuropil of the future antennal lobe is surrounded

by a glial layer. This is also the stage, when the first ORN axons enter the antennal lumen and begin their journey towards the CNS. By E12, an antenno-cerebral tract (ACT) is visible, indicating that PN differentiation is proceeding rapidly. At E15, ORN axons enter the AL neuropil, by E18 irregular, darker staining structures can be seen in the periphery of the AL, and at E19, the first spherical glomeruli are apparent, with most glomeruli being evident by E22. Glial cell processes invade the lobe at E18/19, just as the first glomeruli are forming. By E26, mature glomerular structures with a glial wrapping are evident.

1.12.5. Development of Higher Olfactory Centers: Mushroom Body and Lateral Protocerebrum

1.12.5.1. Projection Neuron Axons

In *Drosophila*, embryonically born Projection neurons (PNs) appear to be the functional projection neurons in larvae. When examined in wandering third instar larvae, each embryonically born PN not only sends dendrites into the larval AL, but also its axons into the larval calyx, and beyond, into the LPR (E.C. Marin and L. Luo, unpublished data).

Axons from larva-born projection neurons can be recognized as early as 72 h APF (Jefferis *et al.*, 2004). However, even at the wandering third instar larval stage, these axons, although extending to the MB calyx region, do not extend within the calyx nor do they enter the lateral protocerebrum. This target innervation occurs in the first 50 h APF.

Among all classes of PNs, the development of the DL1 class has been studied most extensively, as it alone can be precisely identified by its birth time. In the absence of suitable class-specific enhancer trap lines, other PNs must be identified by the glomerular target of their dendrites, which are not identifiable until 50 h APF (see Section 1.12.4.3). In adults, each DL1 neuron exhibits a stereotyped branching pattern within the LH (Marin *et al.*, 2002). As soon as the axon enters the lateral horn, there is a bifurcation, giving rise to a major branch extending continuously laterally towards the lateral edge of the LH, and a dorsal branch projecting to the dorsal-medial corner of the LH. When and how does this branching pattern develop? Time-course analysis of single cell MARCM clones (Jefferis *et al.*, 2004) indicates that the lateral main branch develops first, reaching the lateral edge of the lateral horn before 24 h APF. In the next 6 h or so, the dorsal branch extends as a collateral. The DL1 axon branches in the MB calyx can be visualized at 12 h APF as sprouts, and are resolved into distinct branches at 18 h APF. In both the MB calyx and lateral horn, axon branches can be seen to exhibit numerous filopodial structures in early pupa; however, stable branch structures resembling those of adults are evident at 50 h APF, before the first OR expression can be detected. This would suggest that the establishment of PN axon connection specificity is independent of patterned sensory input.

A first step has been made in the genetic analysis of these stereotyped PN axonal projection patterns. Komiyama *et al.* (2003) found that in homozygous *acj6*$^{-/-}$ PNs of the DL1 class, the highly characteristic dorsal branch in the lateral horn is absent or greatly shortened, whereas the lateral branch is largely unaffected. Expression of an *acj6* rescue transgene, specifically in these mutant PNs, largely rescued this axonal targeting defect. In contrast, expression of Drifter (Dfr) in *acj6*$^{-/-}$ PNs qualitatively enhanced the phenotype, leading in some cases to novel axonal termination patterns. These results suggest two interesting hypotheses: (1) that the specific dendritic and axonal connectivities of PNs may be coregulated by a common transcriptional control system; and (2) that similar downstream effector molecules (such as cell surface proteins) may participate in dendritic and axonal wiring specificity in the antennal lobe and lateral horn, respectively.

1.12.5.2. Mushroom Body Neurons

1.12.5.2.1. Neurogenesis In *Drosophila*, mushroom body (MB) neurons originate from four neuroblasts per hemisphere (Ito and Hotta, 1992), which begin to divide at embryonic stage 9 (of 17) (Noveen *et al.*, 2000). Initial rounds of division generate approximately 60–80 neurons per hemisphere by stage 14 (Noveen *et al.*, 2000); this indicates that each neuroblast is dividing about once per hour. At this point, most other neuroblasts (approximately 80 in the central brain) show a clear pause in proliferation between the embryonic and larval stages (Ito and Hotta, 1992). However, the four MB neuroblasts (and one additional neuroblast located lateral to the antennal lobe) are unusual, in that they divide continuously throughout embryonic and larval development (Truman and Bate, 1988; Ito and Hotta, 1992). The total number of MB neurons generated during embryogenesis has not been accurately determined, but must be less than 300 neurons per hemisphere, since that is the number of axons that can be observed in the peduncle in the first instar larvae (Technau and Heisenberg,

1982). Furthermore, MB neuroblasts are unique in continuing to proliferate beyond a general cut-off of about 30 h APF – they only eventually terminate division at about 90 h APF, shortly before eclosion as an adult (Ito and Hotta, 1992). Indeed, in other insect species including the cricket, *Acheta domesticus*, mushroom body neurogenesis has been found to persist even into the adult (Cayre *et al.*, 1996).

What are the final products of these four neuroblasts? Further studies by Ito *et al.* (1997) showed that each neuroblast generated an apparently identical clonal unit of approximately 500 neurons in the adult, for a total of 2000 per hemisphere, which is consistent with earlier studies (e.g., Technau and Heisenberg, 1982). Each clonal unit consists exclusively of intrinsic MB neurons (Ito *et al.*, 1997) and a number of glial cells near the MB neuron cell body region (Ito *et al.*, 1995).

By a combined single cell labeling and clonal analysis technique, Lee *et al.* (1999) were able to demonstrate that during larval and pupal development, each neuroblast gives rise sequentially to the three major classes of MB neuron postulated by Crittenden *et al.* (1998) (introduced in Section 1.12.2.2.4 above). During the first 3 days of larval development, the neurons innervating the adult γ lobe are born. Neurons that will innervate the adult α' and β' lobes are born between 3 days and shortly before puparium formation (4.5–5 days after larval hatching). Finally, during pupal life, neurons that will innervate the larval α and β lobes are born (**Figure 13**).

Embryonically born MB neurons are most likely γ neurons similar to those born in early larvae. This is based on their sharing similar GAL4 lines (such as GAL4-201Y, which is γ neuron specific until late pupa) and their similar axon pruning behavior during metamorphosis (see Section 1.12.5.4.3). This sequential generation of different MB neuronal types turns out to be a general phenomenon, which has been observed in *Apis* (Farris *et al.*, 1999), *Periplaneta* (Farris and Strausfeld, 2001), and *Acheta* (Malaterre *et al.*, 2002).

It is generally thought that, in the *Drosophila* CNS, the cell division pattern is such that a neuroblast undergoes asymmetric division, generating a new neuroblast and a ganglion mother cell, which divides once more to give rise to a pair of postmitotic neurons (**Figure 10**). This scheme of cell division has rarely been rigorously proven, but in MB neuroblasts it is most certainly the case, at least for divisions shortly after larval hatching. When applying the MARCM technique in conjunction with a GAL4 line that appears to label all MB neurons (GAL4-OK107), three types of clones have been observed. Neuroblast clones and two-cell clones are generated at the same frequency, reflecting the random segregation of the GAL80 repressor to one of the two daughter cells during neuroblast division. Single cell clones, presumably generated during ganglion mother cell division, are also observed but at a different frequency (**Figure 11** and Lee *et al.*, 1999). As development proceeds, the frequency of neuroblast/two-cell clones decreases compared to single cell clones, likely reflecting changes of accessibility to Flp/FRT mediated mitotic recombination due to changes in cell cycle length. Ito *et al.* (1997) estimated that for the four MB neuroblasts to generate 500 MB neurons, they need to divide on average every 55 min, continuously from newly hatched larva to late pupa. Perhaps, because of this demand and the relative ease with

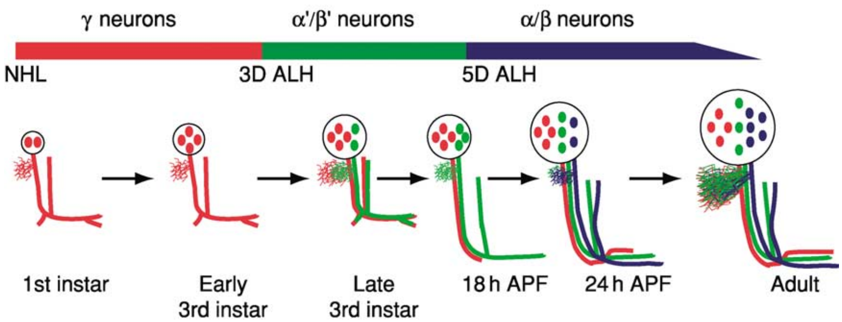

Figure 13 Development of *Drosophila* MB neurons. Each MB neuroblast divides asymmetrically over the course of embryonic to late pupal life. During that time, three distinct major classes of MB neurons are generated, which are named for the adult MB lobes that their axons innervate. Thus, γ neurons are born during embryonic and early to mid larval stages and constitute the larval MB, then α'/β' neurons are born and, finally, α/β neurons. Note that γ neurons initially extend two branches during larval stages, but subsequently prune back both the dorsal and medial branches of axons as well as all dendrites, before re-extending adult-specific dendrites and axon branches only to the medial γ lobe. NHL, newly hatched larva; ALH, after larval hatching; APF, after puparium formation. (Adapted from Lee, T., Lee, A., Luo, L., **1999**. Development of the *Drosophila* mushroom bodies: sequential generation of three distinct types of neurons from a neuroblast. *Development 126*, 4065–4076.)

which defects in MB neuroblast proliferation can be identified by looking at axonal projection patterns in the adult, mutations in many genes have been linked to MB proliferation, including those previously identified based on miniature MBs (Melzig *et al.*, 1998; Guan *et al.*, 2000); Rho GTPases and other actin cytoskeleton regulators (Awasaki *et al.*, 2000; Lee *et al.*, 2000b; Billuart *et al.*, 2001); microtubule motors and their regulators (Liu *et al.*, 2000); genes implicated in chromatin remodeling (Scott *et al.*, 2001a); members of the ubiquitin proteasome system (Watts *et al.*, 2003); and ~1 in 10 chromosomes treated with a moderate dose of ethyl methane sulfonate (EMS) (Reuter *et al.*, 2003). In several cases, neuroblast proliferation defects have been more rigorously proven using BrdU incorporation experiments (Lee *et al.*, 2000b; Liu *et al.*, 2000; Scott *et al.*, 2001a).

1.12.5.2.2. Morphogenesis Because of the complex morphological development of different classes of MB neurons and the ease with which MARCM analysis can be carried out, MB neurons in *Drosophila* have been used as a model system to study different aspects of neuronal morphogenesis. These studies have contributed to our general understanding of morphogenetic mechanisms that can be applied to neurons in other structures and in other organisms. Here only those studies are summarized that reveal special features of the morphogenesis of the MB neurons themselves.

Like most invertebrate CNS neurons, MB neurons in *Drosophila* are unipolar. To recap their structural features described in Section 1.12.2.2.4 above, each neuron extends a single process from the cell body. Shortly after leaving the cell body, the process gives off several collaterals, which extend and generate further branches, giving rise to the calyx or dendritic field of MB neurons. The main process continues to extend anteriorly into the peduncle and becomes the axon (**Figure 5**). Given that MB neurons come from four neuroblasts, do they give rise to four separate units, or are processes from these four neuroblasts intermingled? Zhu *et al.* (2003) found that in wandering third instar larvae, dendrites from each neuroblast clone occupy the entire calyx, indicating that dendrites from the four clonal units intermingle. However, after pruning and re-extension during metamorphosis (see Section 1.12.5.4.2), γ neuron dendrites from each neuroblast clone occupy one-quarter of the dendritic area occupied by the entire γ neuron population, and pupal born α/β neurons likewise obey their clonal boundary, so that the calyx exhibits a fourfold symmetry, with dendrites of MB neurons from one neuroblast occupying one-quarter of the field. There appear to be further divisions within each quadrant, with γ dendrites occupying the border and α/β dendrites occupying the center (Zhu *et al.*, 2003). The functional significance of these different patterns of innervation of the calyx may be revealed by detailed comparison with the termination of afferent projection neuron axons.

In contrast, axons from four clonal units are intermingled shortly before entering into the peduncles in both larvae and adult (Ito *et al.*, 1997). The sequential generation of neuronal types also has its analog in the layered organization of axons in the peduncle and lobes. Results using either a slow maturing red fluorescent protein (Verkhusha *et al.*, 2001), or birth-dating studies with the MARCM system (Kurusu *et al.*, 2002) have demonstrated that in larval lobes, newly born MB neurons project their axons into the core, while peripheral layers contain earlier born neurons. This layered structure is most easily observed in peduncles, but it is also preserved in the two larval lobes; this concentric organization gradually evolves into the adult organization with two separate dorsal lobes and three separate medial lobes.

One of the most prominent morphological features of most MB neurons is their bifurcated axonal structure, with prominent branches in a dorsal and medial lobe. In the embryo, this appears to arise by collateral formation, as Noveen *et al.* (2000) demonstrated using 1,1′-dioctadecyl-3,3,3′,3′-tetramethyl lindocarbocyanine (DiI) labeling of embryonic MB neurons. At embryonic stage 14 (~11 h out of 22 h of embryonic development), a rudimentary peduncle is evident. By stage 16, ~3 h later, a distinctive right angle turn is evident, as axons change course forming the medial lobe. Only by late stage 17 (~ 20 h of embryonic development) is the dorsal lobe evident. Since these were mass labeling studies, it does remain possible that there is an early embryonic MB neuron population that is unbranched and innervates the medial lobe only, which is followed later in embryonic development by a class of neurons with bifurcated axons. Single cell labeling could rule out this alternative explanation.

Does axonal branching in the adult follow a similar logic? The clonal analysis studies of Lee *et al.* (1999) found no signs of asynchronous development of the two axon branches, either of larval neurons or of adult specific α′/β′ or α/β neurons. However, for technical reasons, it was not possible to visualize single cells earlier than 24 h after their birth, so it remains possible that a collateral branching event could occur within this window. A more recent study has provided a possible molecular insight

into the branching process (Wang *et al.*, 2002). A mutation with defective MB branching was isolated in a mosaic screen (in which a small number of homozygous mutant MB neurons are inspected in an animal, which is otherwise heterozygous for the mutation and probably phenotypically wild-type). In this mutant, which was identified as an allele of the Dscam axon guidance receptor (Schmucker *et al.*, 2000), unbranched γ neurons appeared unaffected, but branched α/β neurons showed more branching than wild-type. The excess branches of these single cell mutant clones also distributed themselves randomly between the α and β lobes, rather than distributing themselves evenly between the lobes. Thus, it was postulated that Dscam may mediate a repulsive interaction between sister branches and, in so doing, ensure these enter different lobes, thereby preventing multiple branch formation (Wang *et al.*, 2002). This interpretation makes most sense if α/β neuron axon branching occurs through growth cone splitting rather than collateral branching, a notion yet to be proven.

Further insight into axon branching was obtained in the analysis of Rac (related C3 botulinum toxin substrate) GTPases in MB axon development. Rac GTPases were found to be essential for axon growth, guidance, and branching (Ng *et al.*, 2002a). In neuroblast clones, where hundreds of neurons are homozygous mutant for a given combination of Rac GTPases and exhibit branching defects, it was found that all mutant axons enter either dorsal or medial lobes. They almost never distribute themselves into two populations entering two different lobes, as if the axons were making their decisions together. The existence of such a "community effect" was further supported by the finding that, often, homozygous mutant axons could cause their heterozygous (and phenotypically wild-type) neighboring axons to exhibit the same guidance or branching errors; conversely, the presence of wild-type axons could, to some extent, reduce the error rate of mutant axons.

MB neurons were used to demonstrate the notion that there are dedicated signal transduction pathways for controlling axon branch stability (Billuart *et al.*, 2001). When a negative regulator (p190RhoGAP) for an axon retraction pathway involving small GTPase RhoA is inhibited, MB axons undergo retraction. Interestingly, the dorsal lobes are preferentially retracted compared with the medial lobes; the mechanism for this selective sensitivity is unknown. The activity of p190 RhoGAP could be modulated by integrin, previously shown to be required for MB mediated memory (Grotewiel *et al.*, 1998), so the retraction pathway could be used in the structural plasticity that underlies memory (Billuart *et al.*, 2001). In this regard, it is noteworthy that the dorsal lobe has been especially implicated in mediating long-term memory (Pascual and Preat, 2001).

1.12.5.3. Lateral Protocerebrum

Given that relatively little is known about the cellular components of the LH, and that those neurons that have been identified are quite heterogeneous, it is unsurprising that our knowledge of LPR/LH development is very limited. The existing information centers essentially exclusively on the afferent antennal lobe projection neurons, which was summarized in Section 1.12.5.1 above.

1.12.5.4. Variations

1.12.5.4.1. Development of other MBs The development of the MBs has been investigated more intensively in *Drosophila* than any other insect species. However, important results have been obtained in the cricket and the cockroach (as examples of holometabolous insects) and the honeybee (where the MBs are numerically almost three orders of magnitude more complex), among others. There are many developmental similarities to *Drosophila*, including the extended period of MB neurogenesis compared to the rest of the brain (*Acheta*: Cayre *et al.*, 1996; *Apis*: Farris *et al.*, 1999; Ganeshina *et al.*, 2000); a layered birthdate organization arising from cell bodies that are pushed away from the center by newly born MB neurons (Farris *et al.*, 1999); and the development of axons (i.e., lobes) preceding dendrites (calyx) (Farris *et al.*, 1999).

Despite the similarities in MB development between these species, there are also substantial differences. Comparing, first of all, *Apis* and *Drosophila*, one striking difference is the absence in *Apis* of any embryonic development of the mushroom body. Fly larvae are born with small but functional mushroom bodies, while it is the third day (out of 8) of larval development in bees before any MB neuropil can be observed (Farris *et al.*, 1999). It has been suggested that this relative timing difference between the two species may be due to their different larval lifestyles (Farris *et al.*, 1999). Fly larvae must immediately fend for themselves and locate food sources, whilst bee larvae are fed by nurse bees within the colony. This late generation of MB neuropils correlates with the different patterns of neurogenesis in *Apis* (Farris *et al.*, 1999). At the peak of neurogenesis, around the seventh day of larval development, there are 1000 active neuroblasts in each hemisphere, evenly divided between a medial and a lateral cluster. This large number of neuroblasts (Nbs) is presumably

required to generate the huge mushroom bodies of the adult bee, which consist of some 170 000 neurons (see Section 1.12.2.3.3 above). This late population of neuroblasts originates from an earlier population of 90 or fewer neuroblasts per hemisphere (i.e., 45 per cluster), which are present in the newly hatched larva. Again, in contrast to *Drosophila*, there is initially almost no asymmetric division of these neuroblasts; rather, there are symmetric divisions that expand the neuroblast population. The vast majority of neurons in *Apis* are, therefore, generated late in development from this larger Nb population.

There are also differences in the morphogenesis of the MBs, with significant growth of the lobes only evident in bees on larval day 4. From this point on, however, growth seems to be one continuous process (Farris *et al.*, 1999) without any obvious discontinuity in the early pupal stage comparable with the pruning of the embryonic and larval born γ neurons observed in *Drosophila* (Technau and Heisenberg, 1982; Lee *et al.*, 1999). This may again reflect the absence of a significant larval requirement for higher olfactory function in bees.

The development of MBs in *Periplaneta* (a hemimetabolous insect) is more likely to represent the evolutionarily basal state. In cockroaches, as in *Drosophila*, a small MB is already fully formed by the end of embryogenesis. Lifestyle considerations would, of course, require this, since the environment of the cockroach nymph is largely that of the adult. MB neurogenesis proceeds through 9–11 nymphal instars and there is a corresponding steady integration of MB neurons into the fully functional MB. Adult cockroach MBs have an obvious laminar structure; each lamina is composed of a doublet with, for example, different neurotransmitter levels, and laminar divisions are respected by many efferent extrinsic neurons, suggesting that they may be of functional significance (Li and Strausfeld, 1997). Interestingly, these laminae appear serially over development (Strausfeld and Li, 1999), and an integration lamina at the posterior margin of the lobe is constantly regenerated at each nymphal stage by the arrival of more immature MB neurons (Farris and Strausfeld, 2001). This mode of development may allow a complex MB structure to be built up gradually, in comparison to the small number of sharper transitions seen in *Drosophila* development (Farris and Strausfeld, 2001).

1.12.5.4.2. Developmental plasticity: metamorphosis As described earlier (Section 1.12.5.2.1 above), *Drosophila* MBs are in essentially continuous development, from the mid embryo until late pupa. During this time, a substantial reorganization of the whole brain occurs, as pupal metamorphosis proceeds. Early electron micrograph studies by Technau and Heisenberg (1982) suggested that there was an abrupt 40% reduction in the number of axons in the MB peduncle during the first day of pupal development. The number of MB neuron cell bodies did not change substantially at this time, suggesting that axons were pruned, while their cell bodies remained alive. A more recent study using enhancer traps labeling different subsets of MB neurons has confirmed that large-scale reorganization takes place (Armstrong *et al.*, 1998). Furthermore, this study demonstrated that different lobes of the adult MB have different origins during metamorphosis. For example, hydroxyurea, which is toxic to dividing cells, was fed to newly hatched larvae, resulting in arrest of the five neuroblasts (Nbs) dividing at this time and, consequently, almost complete absence of the normal MB neuron populations. The small number of remaining neurons were assumed to be of embryonic origin and projected solely to the γ lobe; indeed, the vertical lobes were completely absent. Thus, it would seem that the γ lobe is specific to early-born neurons. The subsequent analysis of Lee *et al.* (1999) using the MARCM system confirmed and extended these findings with single-cell resolution. The first-born neurons, γ neurons, were found to degenerate extensively at metamorphosis, so that by 18 h APF their bifurcated axons had been pruned back to their original branch point at the end of the peduncle; this retention of the peduncle is in contrast to the earlier findings of Technau and Heisenberg (1982), who concluded that peduncular axons were also pruned. In contrast, the two later born classes (α′/β′ and α/β) showed no axonal reorganization at metamorphosis. Re-extension was rapid, with regenerated axons extending substantially by 24 h APF and extension appearing complete by 36 h APF (**Figure 13**).

What is the molecular basis of this axonal pruning? Metamorphic processes in many insects are triggered by the steroid hormone 20-hydroxyecdysone (termed hereafter ecdysone). This is released in specific pulses from the prothoracic gland, binds to a receptor protein, the ecdysone receptor (EcR), in conjunction with a coreceptor, ultraspiracle (Usp), and thereby triggers transcriptional changes associated with metamorphosis (review: Thummel, 1996) (see also **Chapter 3.1**; **Chapter 3.5**; and **Chapter 2.4**). A forward genetic screen for mutants that failed to undergo MB γ neuron remodeling, and a candidate gene approach, converged on the Usp coreceptor, indicating that this event is indeed

controlled by ecdysone (Lee *et al.*, 2000a) (see also **Chapter 2.4**). The *usp* mutant neurons failed to remodel, but retained their larval branching pattern. Since this approach used the MARCM system, in which only small clones of labeled cells were mutant, this requirement for Usp is clearly cell autonomous, i.e., it is required for a transcriptional program directly in MB neurons. Why is it specifically the γ neurons, rather than the coexisting α′/β′ neurons, that remodel? This same study also identified the ecydsone receptor subtype B1 as the relevant Usp partner, and demonstrated that it was expressed in γ neurons, but not in α′/β′ neurons.

Working further upstream, Zheng *et al*. (2003) showed that transforming growth factor beta (TGF-β) signals received by Baboon (Babo), a type 1 receptor (see Shi and Massague, 2003 for a review of TGF-β signaling), and dSmad2 its transcriptional effector, are required for high-level expression of EcR-B1 and for γ neuron remodeling; the cognate ligand is likely to be dActivin. EcR-B1 only turns on in γ neurons in mid-third instar, shortly before the ecdysone pulses that trigger the first events of metamorphosis, but after the last of the pulses that trigger molting between larval stages. It is an attractive hypothesis that a TGF-β signal might temporally restrict *EcR-B1* expression; however, the identified signaling components are not expressed with the appropriate temporal specificity. Interestingly, although Baboon, the type 1 receptor, was necessary for remodeling and *EcR-B1* expression, an ectopically expressed dominant active receptor was not sufficient to activate *EcR-B1* expression. Thus, MB neurons may have some temporal specificity, of unknown mechanism, in their ability to respond to a TGF-β signal.

The studies described above focus on signals that initiate MB γ neuron pruning. What is known about the execution phase? Watts *et al*. (2003) have described the cellular events of pruning. They conclude that axonal pruning occurs by a process of local degeneration, rather than axonal retraction, in which γ neuron axons start to fragment at 8 h APF. By 18 h APF most of the cellular debris has been cleared, and the neuron is ready to begin re-extending a new axon. What molecular events might underlie this process? Watts *et al*. found two clues. Following the expression of a number of different cellular markers in degenerating γ neurons, they noted that microtubule destabilization preceded any change in axonal morphology, suggesting that this may be an early step in pruning. They also identified the ubiquitin proteasome system as a key regulator of pruning. Overexpression in MB neurons of a yeast ubiquitin protease, UBP2, which should oppose the ubiquitination process, dramatically decreased pruning, so that γ neurons retained their larval branches in the adult. Similarly, loss-of-function mutations in the E1 ubiquitin activating enzyme Uba1 and the proteasome components Mov34 (Moloney leukemia virus-34 proviral integration homolog) and Rpn6 (regulatory particle non-ATPase6) also autonomously blocked pruning. In relation to the earlier results concerning initiation of axon pruning, Watts *et al.* also demonstrated that these mutants did not interfere with normal expression of EcR-B1 in γ neurons. It would, therefore, seem that the requirement for the ubiquitin proteasome system is downstream of the ecdysone signaling and closer to the point of execution. Intriguingly, both the requirement for ubiquitin proteasome system function and the early destabilization of microtubules have recently been demonstrated in the process of Wallerian degeneration, which occurs when mammalian axons are severed (Zhai *et al*., 2003). Thus, MB pruning may provide a powerful model system to study axon degeneration, one of the hallmarks of many neurodegenerative diseases.

In conclusion, in *Drosophila*, pruning of the axons and dendrites of the early-born γ neurons allows them to transition from their larval to adult function. Substantial progress has already been made in understanding both the cellular mechanism, which seems to be a local degenerative process, and the underlying molecular mechanisms, which include TGF-β signaling, ecdysone signaling, and the ubiquitin proteasome system. Given the widespread use of ecdysone in insects and some molecular parallels with vertebrates in the execution phase, these insights are likely to be of general relevance.

1.12.5.4.3. Adult plasticity Many insect neurobiologists, and certainly vertebrate neurobiologists, when thinking of insect nervous systems, have a tendency to emphasize the degree to which the nervous system undergoes extremely stereotyped, precisely genetically programed development. However, there have been numerous reports of quite substantial plasticity in insect brains, especially in the MBs.

Structural plasticity can be considered at different levels, from neurogenesis to remodeling of neuronal arbors, to synaptic plasticity, which presumably requires changes evident at the molecular level, if not at the level of cellular morphology. For example, during the well-studied process of olfactory learning in *Drosophila*, it is generally assumed that there must be synaptic potentiation at MB synapses (see **Chapter 3.15**). However, whether potentiation

occurs at input or output synapses is admittedly less clear. However, other forms of structural plasticity that have been observed are inherently rather more surprising.

In *Drosophila*, there have been numerous studies relating experience during development, or as an adult, to the status of the MBs. For example, Heisenberg *et al.* (1995) report that larval crowding can actually cause an increase in MB neuron number of about 20%, and a corresponding volume change in the calyx. These changes are not just confined to development, since neuropil volume changes were also reported in adult animals. For example, differences in MB calyx volume were described for pairs of flies reared together in the second week of adult life: same sex pairs had larger calyces. While these changes are reproducible, their behavioral significance is often somewhat obscure.

A series of studies in the honeybee gives an example of structural plasticity with a more obvious behavioral relevance. An initial report indicated that the volume of MB neuropil was some 15% greater in forager bees than in 1 day old adults (Withers *et al.*, 1993); somewhat curiously, the cell body volume actually decreases in these older animals, so that there is a substantial change in the ratio of MB neuropil to cell body volume. Honeybees transition through several behavioral stages from newly eclosed adult to nurse bee (remaining in the hive and caring for larvae), to foragers (leaving the hive and foraging for food). The neuropil/cell body ratio is also greater in foragers than in nurse bees, suggesting the possibility that these changes may be directly related to a bee's behavioral status (caste). However, since foragers in a normal colony are typically a week older than nurse bees, the effect of age must be separated from caste. By generating a synchronized colony, Withers *et al.* (1993) were able to confirm that these volume differences were still present in age-matched nurse and forager bees. Subsequent results have indicated that changes in neuropil volume are not dependent on neurogenesis (Fahrbach *et al.*, 1995) and have both experience-dependent and independent components (Fahrbach *et al.*, 1998). At the cellular level, a recent report suggests that the neuropil volume changes can be related to the morphology of individual MB neurons: in older animals and even in age-matched foragers compared with nurse bees, MB dendrites were longer and more highly branched, especially in regions of the calyx receiving visual input (Farris *et al.*, 2001).

In contrast to the strictly morphogenetic changes just described, in the cricket, *A. domesticus*, it has been reported that neurogenesis persists in the adult (Cayre *et al.*, 1996). This appears to be of functional significance, since the same group has more recently reported that sensory input can modulate this adult neurogenesis. Under enriched conditions, females that were reared in large cages, could hear male songs and smell environmental odors; impoverished conditions included solitary rearing in small cages in the dark. A 25% reduction in MB neurogenesis, as assayed by BrdU incorporation, was noted in females in impoverished conditions compared with those from the enriched environment (Scotto Lomassese *et al.*, 2000). This effect can still be observed in the absence of the corpora allata (their product, juvenile hormone, is known to have a neurogenic effect) (Scotto-Lomassese *et al.*, 2002). Finally, in a nice experiment, unilateral visual deprivation (by painting over one eye) led to a significant but unilateral decrease in neurogenesis (Scotto-Lomassese *et al.*, 2002). This suggests that the neurogenic effect may be a direct result of neuronal activity levels rather than being mediated, for example, by a centrally released hormone.

1.12.6. Conclusions

1.12.6.1. Among Insects

This review has focused, to a great extent, on the development of the olfactory system in *Drosophila*. To what extent are developmental mechanisms conserved among different insect species? The basic unit of the peripheral olfactory system, the sensillum, is structurally extremely conserved, and it is to be expected that the details of the developmental mechanisms will also show conservation. Even the typical differences between holometabolous and hemimetabolous insect development may not be so great, when considered at this level. Will the molecular findings of expression of a single specific olfactory receptor (OR) in different ORNs and the convergence to individual glomeruli be generalizable? Again, the authors would predict yes; the pheromone detection system of moths (see **Chapter 3.15**) gives an example, in which this seems very likely to be the case. For example, in *Agrotis segetum*, ORNs responding to two identified pheromone components project to discrete glomeruli in the MGC; an inhibitory compound is detected by ORNs projecting to a third MGC glomerulus (Hansson *et al.*, 1992). Furthermore, the findings from AL imaging studies suggest that the nature of olfactory coding is similar among different insect species (Section 1.12.2.1.2). Another specific case is the glomerulus V, which is CO_2-responsive in *Drosophila* (M. de Bruyne, unpublished data).

CO_2-responsive neurons of the labial pit organ in *M. sexta* also project to a single, distinctive ventral glomerulus in the AL. Interestingly, in *Drosophila*, the CO_2-responsive neurons are on the third antennal segment (de Bruyne *et al*., 2001). Thus, in this instance, the central target of a particular ORN class may be more conserved than its peripheral location. It should be noted that uniglomerular projections of ORN classes cannot be completely universal, given the anatomy of the locust system (Section 1.12.2.3.2).

The development of the antennal lobe and, in particular, AL glomeruli offers another interesting point of comparison. Although the antennal lobe in holometabolous and hemimetabolous insects develops at completely different times, similar principles have been noted: for example, the requirement of ORN axons for glomerular formation and the extension of glia or glial processes into the antennal lobe during glomerular formation. There are, however, likely to be numerous differences. Thus, for example, extension of glial processes into the lobe appears to occur much later in *Drosophila* than in *Manduca* and *Periplaneta*. Similarly, in *Manduca*, ORNs form protoglomeruli apparently without associating with other cell types, while in *Periplaneta*, ORN axons seem to develop in association with dendrites of central neurons. In *Drosophila*, protoglomerular accumulation of ORNs may exist, but the resolution of existing studies is not high enough to confirm or contradict this. Finally, the glial sorting zone identified at the entry to the developing *Manduca* AL has yet to be observed in other insects. Such a sorting zone may be particularly important given the rapid arrival of up to 300 000 ORNs in *Manduca*; there are only 1300 ORNs in *Drosophila*, while the AL of *Periplaneta* is the target of a similar number of ORNs as for *Manduca*, but these ORNs arrive over months of embryonic and nymphal development. If such issues do arise because of differences in the scale and intensity of development, it is possible that they might also be present in the development of vertebrate olfactory systems: *Manduca* glomeruli are quite comparable in size to rodent glomeruli, albeit about 10- or 20-fold less numerous.

At this stage, the general significance of the *Drosophila* observations on prespecification/sequential generation of different PN types (Section 1.12.4.2.1) is not certain. The authors would strongly suspect the existence of such mechanisms in other insects, both because of an expected conservation of basic developmental mechanisms and because this is an elegant way to allow the persistence of labeled olfactory lines deep into the nervous system.

In the MBs, as mentioned in Section 1.12.5.4.1, sequential generation of different cell types is also a common theme. Not that much is yet known about the functional significance of these different cell types, although different MB lobes (and consequently MB neurons born at different times) have been linked to specific memory processes in *Drosophila* (e.g., Pascual and Preat, 2001). From a comparative stance, the development of axon lobes and then dendritic calyx, and a concentric arrangement of cell bodies according to birthdate, have been identified by Farris and Strausfeld (2001) as common developmental themes among both holometabolous and hemimetabolous insects. As usual, however, the more gradual development of the latter does have consequences, for example, in the laminar organization of cockroach MBs (Section 1.12.5.4.1).

In conclusion, the insect world encompasses an enormous variety of olfactory systems. It could be argued that the structure and organization of peripheral sensory appendages (but perhaps not individual sensilla) is most variable among different species, while the logic of antennal lobe organization is very similar. While there may be substantial differences in scale and some differences in the timing of the cellular events accompanying olfactory development, mechanisms are likely to be broadly conserved and the advent of molecular studies will presumably only strengthen this impression.

1.12.6.2. Future Directions

The last few years have witnessed substantial advances in our knowledge of olfactory system development in insects, particularly *Drosophila*. The identification of olfactory receptors (ORs) (thanks to the *Drosophila* and more recently the *Anopheles* genome projects) reveals organizational principles in the peripheral olfactory system (Section 1.12.2.1). Furthermore, the development of genetic tools allowing tracing of neuronal projections in both groups and at the single cell level, have also contributed to this progress. The pace of discovery is expected to increase even more now that these initial successes have attracted a large group of scientists to research the olfactory system. In this section, as in many others, the focus is first on *Drosophila* and then on other insects.

What do we envisage as areas of special interest in olfactory system development? One ultimate goal of developmental biology is to understand the generation of an organ or system as it pertains to its function. In olfaction, this means understanding the developmental basis of odorant discrimination, recognition, and innate and learned olfactory

responses. At the first level, in the antenna and the maxillary palp, each of the 1300 ORNs probably expresses one specific member from a group of ~50 ORs, thereby creating specific channels of information processing. How is olfactory receptor expression choice made during development? How is this developmental decision related to general pattern formation in the AL? With the tools created by the cloning of OR genes, answers to these questions are in sight.

Much progress is expected in our understanding of wiring specificity will be made in the antennal lobe, the first olfactory relay. The convergent projection of ORN axons to specific glomeruli according to the OR they express, and the independent determination of PN dendritic glomerular targets according to their lineage and birth order, beg the question as to how this extraordinary wiring specificity is achieved. With the genetic tools in hand, it should be possible in the near future to decipher the logic behind how each individual ORN selects one from among ~50 glomeruli as its axonal target, how each individual PN selects one from these ~50 glomeruli as its dendritic target, and how these choices are coordinated. The logic used to achieve wiring specificity in the olfactory system could well be applied to many other parts of the brain.

Going deeper into the brain, it will be fruitful to examine how the wiring specificity of projection neuron axons in central targets is coordinated with their dendritic targets at the antennal lobe. To address this question more thoroughly, and to understand how olfactory information is further processed in higher brain centers, it is essential to identify third-order neurons with which PN axons form synapses. One major class of third order neurons has already been identified as the MB neurons; studying connection specificity between PNs and MB neurons will be important. A second class of third order neurons are the putative LH output neurons that synapse with PN axons in the lateral horn, the nature of which is still elusive. Developing new technologies to identify these neurons, as well as neurons downstream from lateral horn output neurons and mushroom body neurons, will remain a future challenge. Having identified these lateral horn neurons, the development of wiring specificity in both these higher structures should be amenable to study; comparisons of the logic used here versus in the antennal lobe will be interesting. Finally, a long-term goal must be to trace the process from sensory detection to integration and behavioral (motor) output. Olfaction can be characterized as an organizationally shallow sense – it probably only takes two synaptic levels to move from sensory stimulus to percept. Olfactory circuits should, thus, be particularly amenable to the tracing out of circuits that mediate an organism's behavioral response as well as understanding its developmental and genetic basis.

While, at least at the gross level, the olfactory system appears to be hard-wired and, as such, the substrate for innate behavior, it is entirely possible that experience will modify the strength or presence of connections at the level of individual synapses. Indeed, olfactory learning and memory is one of the most robust and best-characterized behavioral paradigms in *Drosophila*. With the basic wiring diagram characterized, it is now possible to examine how experience will change wiring. To what extent does experience dependent rewiring share mechanistic similarity with genetically specified wiring during development?

Another interesting future direction is the integration of the molecular genetics of olfactory development with olfactory physiology and behavior. Recent development of electrophysiological and optical imaging techniques starts to illuminate how olfactory information is being processed along the central pathway. These techniques could also be used to study the consequences of altered wiring using molecular genetic manipulation. Ultimately, it will be extremely interesting to study how precise genetic manipulation leads to altered physiological responses and changes in animal behavior, thus yielding insights into how genes, neurons, and circuits control behavior. Similar techniques may be applicable in studying the role of species specific genetic variation in other insects.

Lastly, an important future direction is the spread of molecular genetic approaches to other insects. The completion or near completion of genomic DNA sequencing in the silkmoth, ant and honeybee should allow identification of odorant receptor repertoires, as has been shown in *Drosophila* and *Anopheles*. Transgenic technologies using transposon or retroviral approaches have recently been demonstrated in a wide variety of insect species. Such tools could allow the labeling of specific classes of ORNs as well as study of their central projections in these insects. Furthermore, double-stranded RNA interference techniques to knockdown gene function have also become commonplace in the last few years. The availability of these techniques should broaden the experimental horizon so that the special advantages of different model systems can be fully exploited. For example, it would be of great experimental benefit to combine the surgical

manipulations or explant cultures developed in *M. sexta* with genetic manipulation or labeling of precise cell populations.

One fascinating question that may yield to this kind of multisystem approach is an understanding of how the fine organization of the olfactory system in different insects may be related. For instance, it would be extremely interesting to compare the evolution of olfactory receptor number and diversity with glomerular number. Similarly, it will be most interesting to understand how changes in the peripheral sensory array might be reflected in their partner neurons within the CNS. For example, it may be possible to determine if PNs that receive input from orthologous ORs have a consistent molecular identity and axonal projection pattern in higher centers. In short, it can be predicted that insect olfaction should provide fertile ground for investigation at many different levels, from molecules to behavior, both within individual species as well as an exciting system for comparative approaches between species.

1.12.6.3. Note Added in Proof

N-cadherin, in addition to its role in uniglomerular restriction of projection neuron dendritic targeting, also regulates the stability of a specific subset of PN axon terminal branches in the lateral horn (Zhu and Luo, 2004). N-cadherin is also required in ORNs for glomerular formation: the axons of N-cadherin deficient ORNs initially enter the developing antennal lobe but then withdraw to the surface of the antennal lobe, resulting in disruption of normal glomerular development (Hummel and Zipursky, 2004).

Two additional studies shed light on molecules and mechanisms for ORN axon targeting. Loss-of-function analyses as well as misexpression studies indicate that the axon guidance receptors of the Roundabout (Robo) family regulate the glomerular position of ORN axons in the antennal lobe. Robo2 also regulates midline crossing of ORN axons projecting to contralateral glomeruli (Jhaveri *et al.*, 2004). In a second study (Komiyama *et al.*, 2004), it was shown that the POU domain transcription factor Acj6, in addition to its role in PN dendritic targeting, also regulates axon targeting for a subset of ORN classes. Mosaic analyses reveal cooperative targeting between axon terminals of the same ORN classes and hierarchical interactions among different ORN classes. These observations support the emergent idea that the development of highly specific wiring between ORN axons and PN dendrites in the olfactory system involves substantial prepatterning of both ORN axons and PN dendrites through axon–axon and dendrite–dendrite interactions.

Acknowledgments

We thank M. de Bruyne, E.C. Marin, A. Nighorn, A. Ramaekers, and R.F. Stocker for sharing recent unpublished results. For comments on various sections and versions of this manuscript, we are grateful to D. Berdnik, E.C. Marin, A. Ramaekers, R.F. Stocker, R.J. Watts, H. Zhu and A.L. Taylor Tavares, whom we also thank for assistance with the figures. In addition to those mentioned above, we thank L. Oland and P. zur Lage for patiently fielding questions relating to their areas of expertise.

2.1 Myogenesis and Muscle Development

S M Abmayr, L Balagopalan, B J Galletta, and S-J Hong, Penn State University, University Park, PA, USA

2.1.1. Introduction

With recent advances in molecular genetics and cell biology, our progress in understanding the embryonic development of larval body wall muscles in the past 10 or 15 years has outpaced that of the previous four or five decades combined. One of the many insights provided by numerous studies is that fundamental cell fate decisions, at the level of changes in gene expression, occur long before the morphological consequences of myogenesis are visible. It is now clear, for example, that the mechanisms responsible for patterning the musculature and establishing the identity of each muscle fiber act very shortly after myogenic determination. These early cell fate choices dictate an almost invariant pattern of muscle attachment and innervation hours later.

While recent advances have dramatically expanded upon, clarified, or corrected earlier notions, there is no doubt that these advances were built on a solid foundation. Our understanding of embryonic myogenesis and appreciation of muscle pattern were influenced by tedious and time-consuming studies summarized in classic reviews by Poulson (1950) and Crossley (1978). Morphological studies first described the presumptive musculature as inner and outer layers of mesodermal cells that appeared to retain their relative positions in later stages (Poulson, 1950). These layers, the so-called splanchnopleura and somatopleura, were apparent during germ band retraction. The former was thought to give rise to the visceral musculature, and the latter to the somatic muscles. The somatic mesoderm was then observed to separate into dorsolateral and ventrolateral portions, with the ventrolateral portions giving rise to the musculature and the dorsolateral portions giving rise to fat body, circulatory system, and gonadal mesoderm. Later, the segmented ventrolateral domain appeared to remain in close association with the ectoderm and, upon completion of germ band shortening, to be limited to intersegmental regions where the developing syncytia establish contact with the developing apodemes. While the use of molecular probes, genetic tricks, and transgenic technology have suggested some differences, this description remains essentially correct.

Features of differentiated muscle fibers and the first naming of the individual *Drosophila* members of the larval body wall musculature were described in an extensively cited review by Crossley (1978). At the time of the initial fusion events, the multinucleated myoblasts were reported to have sparse endoplamic reticulum, many mitochondria and a large number of microtubules oriented along the longitudinal axis of the syncytia. Based on studies in other insects, these results suggested that the microtubules serve as a scaffold for the assembly of microfilament arrays (Crossley, 1978). No obvious mitoses were reported, though the possibility of limited mitotic events was not eliminated. Consistent with this was the observation that myoblasts in primary cultures undergo only one round of mitosis before differentiation into mononucleate muscle fibers (Bernstein *et al*., 1993). Myofibrils were evident in sections from embryos at 10–11 h, and the musculature was found to be complete in all of its details by 13–14 h. Coordinated muscle contraction becomes apparent by this time. Slightly later, Z bodies were observed. These structures organize into Z-lines in parallel arrays within the microfilament bundles, between 16 and 18 h. With few exceptions, the remainder of our early understanding of insect myogenesis was restricted to structural details of the fully differentiated larval muscles or, more commonly, the adult musculature (Crossley, 1978; Bernstein *et al*., 1993; see also **Chapters 2.2** and **2.3**).

In this review, our aim is to expand upon these early studies and summarize the experimental approaches, results, and concepts that form the foundation of our current understanding of embryonic myogenesis.

2.1.2. Mesoderm Specification and Subdivision

The present volume includes chapters devoted to many different aspects of embryonic development, and includes a discussion of zygotic genome expression and pattern formation (see, for example, **Chapters 1.2**, **1.8–1.10**). Thus, some of the key genes and decisions influencing the formation of the germ layers in the embryo, and their subsequent development, are covered more thoroughly elsewhere. However, as some of the genes that play critical events in the early embryo are also utilized later in myogenesis, we include a brief summary here. We have restricted this discussion to mesoderm specification and subdivision as it relates to the subsequent musculature.

2.1.2.1. Early Mesodermal Events

The larval musculature of *Drosophila melanogaster* derives from the embryonic mesoderm, which is formed by cells that are positioned ventrally in a blastoderm stage embryo. Mesoderm formation is initiated by the establishment of the dorsoventral axis of the embryo, a process that is accomplished by the maternally-provided Dorsal protein, a NF-κB-related transcription factor (see **Chapter 1.2**). A morphogenetic gradient of Dorsal is then generated by transport of the protein from the shared cytoplasm of the syncytial embryo to nuclei along the ventral side of the embryo (Bate, 1993; Belvin and Anderson, 1996). Upon subsequent cellularization, the nuclei of these ventrally-located cells contain high levels of Dorsal while those cells on the dorsal side of the embryo contain much lower levels. This concentration difference then contributes to early positional information in cells of the blastoderm stage embryo that commits them to different fates.

The nuclear localization of Dorsal results in the transcriptional activation of two zygotic genes, *twist* (*twi*) and *snail* (*sna*). Genetic studies have established that mesoderm formation is dependent on the presence of *twi*, which takes its name from the twisted appearance of embryos that attempt to gastrulate in its absence (Simpson, 1983; Grau *et al*., 1984). An abnormal ventral furrow is observed in these mutant embryos, but no mesoderm forms. By comparison, embryos mutant for *sna* exhibit no distinct furrow but do have subtle folds of cells that appear in the ventral region during gastrulation. Similar to the situation in *twi* mutants, mesoderm does not form in *sna* mutant embryos. The *twi* gene, which encodes a basic helix–loop–helix (bHLH)-containing transcription factor, is initially expressed in mesodermal cells at Stage 5 (Thisse *et al*., 1988; Leptin, 1991). This expression generally begins to decline during Stage 11 but persists in a subset of mesodermal cells that are progenitors of the muscles (Thisse *et al*., 1988; Bate, 1993; see Sections 2.1.2.2.2 and 2.1.2.3.1). By Stage 13, *twi* expression is confined to cells that include progenitors of the adult muscles and cells associated with the alary muscles (Bate *et al*., 1991).

The *sna* locus, another Dorsal target gene, encodes a zinc-finger-containing protein (Boulay, *et al*., 1987) that is also detected during Stage 5 (Kosman *et al*., 1991; Leptin, 1991). The key difference between the expression patterns of the two Dorsal target genes *twi* and *sna* is that the *sna* expression pattern exhibits sharp lateral borders that demarcate the boundary between the presumptive

mesoderm and neurogenic ectoderm. While both of these genes are required for mesoderm formation, comparison of the mutant phenotypes of embryos lacking either *twi* or *sna*, and embryos lacking both *twi* and *sna* suggest that the two genes play different roles in mesoderm development. Thus, *sna* is thought to play a predominantly permissive role by repressing nonmesodermal genes in the presumptive mesoderm. By contrast, *twi* appears to act as a transcriptional activator of downstream genes that are required for invagination, patterning, and differentiation of various mesodermal derivatives (Kosman *et al*., 1991; Leptin, 1991). It contributes, for example, to the transcriptional activation of *tinman* (*tin*) in the specification of heart and visceral muscle derivatives and, at high levels, is sufficient to specify cells as somatic muscle (Baylies and Bate, 1996; see Sections 2.1.2.2.2 and 2.1.2.3.1).

Following specification of the mesoderm, the *twi/sna*-expressing cells invaginate through the ventral furrow at gastrulation and form a tube-like structure (Leptin and Grunewald, 1990; Leptin *et al*., 1992). Mesoderm invagination is dependent on the *folded gastrulation* (*fog*) gene (Costa *et al*., 1994), which is expressed in a *twi*-dependent manner in ventral regions of the blastoderm. In *fog* mutants, the concerted apical constriction of mesodermal cells does not occur, leading to their failure to invaginate. As *fog* encodes a secreted protein, it is thought to act as a signal that coordinates apical constrictions of mesodermal cells (Costa *et al*., 1994). Shortly after invagination, as the embryonic germ band extends, mesodermal cells migrate dorsally to form a monolayer just beneath the ectoderm (Leptin and Grunewald, 1990; Leptin *et al*., 1992). This movement of mesodermal cells depends on mesodermal expression of the *Drosophila* fibroblast growth factor receptor, Heartless (Htl)/DFR1 (Shishido *et al*., 1993; Bieman *et al*., 1996 and Gisselbrecht *et al*., 1996; Shishido *et al*., 1997). In *htl/DFR1* mutant embryos, the mesoderm invaginates normally but fails to reach its dorsal destination to receive inductive signals from the ectoderm (Gisselbrecht *et al*., 1996). Understanding how Htl/DFR1 influences the dorsal migration of mesodermal cells awaits identification of the Htl/DFR1 ligand.

2.1.2.2. Segregation of the Visceral and Somatic Mesoderm

Shortly after dorsal migration of the invaginated mesoderm has occurred, the mesoderm is subdivided into units, from which the progenitors of different mesodermal tissues will arise. These tissues include the visceral and somatic musculature, the heart, and the fat body (Dunin-Borkowski *et al*., 1995; Azpiazu *et al*., 1996; Riechmann *et al*., 1997; see also **Chapters 2.6** and **2.9**). It is now clear that this subdivision is accomplished by combinatorial mechanisms that include both mesoderm-autonomous contributions as well as inductive influences from the overlying ectoderm. The overlapping signals derived from each of these mechanisms intersect in defined regions along the dorsoventral and anteroposterior axis. The developmental program of cells within each of these regions is then dictated by the combination of the signals they receive.

2.1.2.2.1. Signaling along the dorsal-ventral axis Dorsoventral patterning of the mesoderm occurs in response to secretion of the *decapentaplegic* (*dpp*) gene product, a member of the transforming growth factor-β (TGF-β) family (Padgett *et al*., 1987), from the dorsal ectoderm (Staehling-Hampton *et al*., 1994; Frasch, 1995). The Dpp signal in turn activates genes specific to the dorsal mesoderm, including *tin*, *bagpipe* (*bap*), and *Fasciclin III* (*FasIII*), that contribute to formation of the heart and visceral musculature. Ectopic expression of Dpp in ventral regions of the embryo, in either mesodermal or overlying ectodermal cells, results in the ventral expansion of the domains of *bap* and *FasIII* expression (Staehling-Hampton *et al*., 1994; Frasch, 1995). Dpp signaling also plays a role in the repression of ventral genes in the dorsal regions of the embryo. Among these is *pox-meso* (*poxm*), which encodes a paired domain-containing protein, and is normally expressed in ventrally-located mesodermal cells that contribute to the bulk of the somatic musculature (Bopp *et al*., 1989). Expression of *bap* and *FasIII* is abolished in *dpp* loss-of-function mutants, but is recovered when Dpp is provided ectopically (Frasch, 1995). In a reciprocal fashion, ectopic Dpp represses expression of *pox-meso* in the ventral mesodermal regions whereas *dpp* loss-of-function mutants exhibit an expanded domain of *pox-meso* (Staehling-Hampton *et al*., 1994). Thus, Dpp plays an inductive role in promoting proper specification of dorsal mesoderm and a repressive role in preventing these cells from being specified as ventral mesoderm.

The homeodomain-containing protein Tin, a target of Dpp, is essential for the formation of the heart, visceral musculature, and dorsal somatic musculature (Bodmer *et al*., 1990; Azpiazu and Frasch, 1993; Bodmer, 1993). The role of *tin* in cardiac development is covered in **Chapter 2.6** in this series, and will not be discussed further herein. Activation of *tin* by Dpp likely occurs through interaction of Dpp with the Dpp receptor Thickveins (Tkv; Yin and Frasch, 1998). Of note, *tin* is also a target of

the bHLH-containing Twi protein (Yin *et al.*, 1997). Specification of the visceral musculature is accomplished by the Tin-mediated activation of *bap*, another homeodomain-protein-encoding gene. Bap is expressed exclusively in the visceral mesoderm, and is essential for differentiation of the visceral musculature (Azpiazu and Frasch, 1993; see Section 2.1.4). Its expression is activated by Tin, and is absent in embryos mutant for *tin* (Azpiazu and Frasch, 1993). As expected from this cascade of expression, the visceral musculature is severely disrupted in embryos lacking *bap*. Interestingly, the presumptive visceral mesoderm can be transformed in these mutant backgrounds into body wall musculature and gonadal mesoderm (Azpiazu and Frasch, 1993).

2.1.2.2.2. Signaling along the anteroposterior axis The anteroposterior subdivision of the *Drosophila* embryo into a series of metameric units, or segments, has been extensively documented in the ectoderm. Similarly, the tissues that differentiate from the somatic and visceral mesoderm reflect a segmental organization and identity. The actual subdivision of the mesoderm into its derivatives occurs along the anterior–posterior axis within each metameric unit.

Dunin-Borokowski (Dunin-Borkowski *et al.*, 1995) examined this subdivision by marking all mesodermal cells with the mammalian cell surface protein CD2, expressed under the control of the *twi* promoter. This approach allowed cells located in different regions of the mesoderm to be followed, such that their subsequent developmental programs could be examined. As a consequence, they determined that the dorsal anterior cells invaginate and become visceral mesoderm. By contrast, both the dorsal and ventral posterior cells become somatic muscle progenitors. Their descriptions were reinforced, in this and other studies, by the examination of expression patterns of a variety of molecular markers for each of the progenitor types in mutant embryos (Dunin-Borkowski *et al.*, 1995; Azpiazu *et al.*, 1996; Riechmann *et al.*, 1997). The regional assignments of cells to different progenitor populations, including those of the visceral and somatic muscles, the heart and the fat body, were revealed by these analyses (Riechmann *et al.*, 1997; **Figure 1**).

Studies have now established that the mesoderm is partitioned along the embryonic anteroposterior axis by the action of the pair-rule genes *even-skipped* (*eve*) and *sloppy-paired* (*slp*) (Azpiazu *et al.*, 1996; Riechmann *et al.*, 1997; **Figure 1**). The *eve* locus encodes a homeodomain-containing protein, while the *slp* locus encodes a paired domain-containing protein (Macdonald *et al.*, 1986;

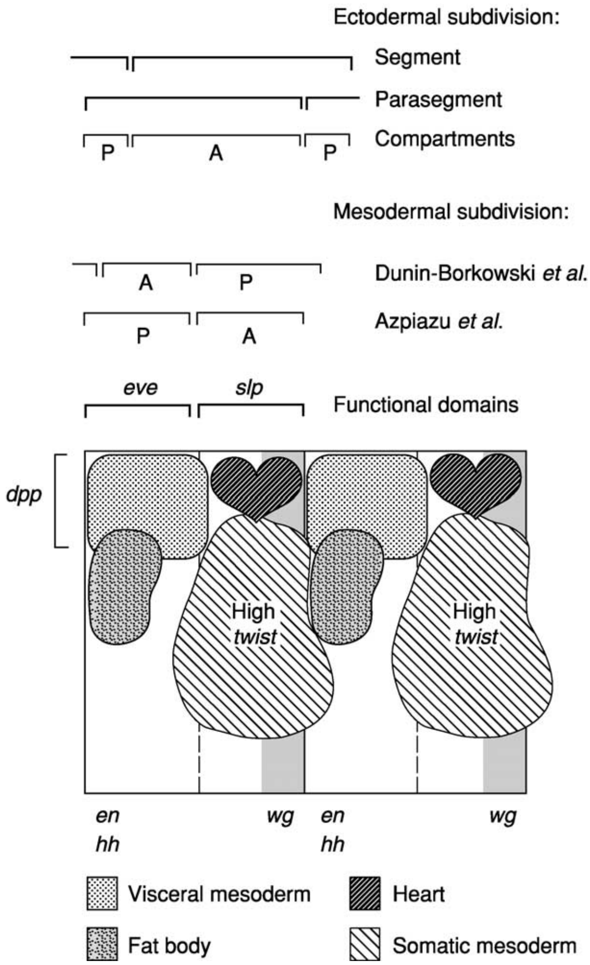

Figure 1 Positions of mesodermal subpopulations. The diagram shows the locations of mesodermal subpopulations relative to the units of subdivision used for the ectoderm (compartments and parasegments), the early mesoderm (A and P according to Azpiazu *et al.*, 1996), later mesoderm (A and P according to Dunin-Borkowski *et al.*, 1995), and the domains of *eve* and *slp* function in the mesoderm. The *slp* domain gives rise to the dorsally located heart precursors and to the majority of somatic muscles. Development of somatic muscles requires the maintenance of high levels of *twist* expression (Baylies and Bate, 1996). In the *eve* domain of each segment, the most dorsally located group of cells gives rise to the visceral musculature. The fat body primordium lies slightly more ventrally. The primordia of the visceral muscles and the fat body overlap the *engrailed* (*en*) and *hedgehog* (*hh*) expression domain, and these genes are necessary for their spatial determination (Azpiazu *et al.*, 1996). The heart primordium and the high Twist domain overlap the *wingless* (*wg*) expression domain and require Wg for their proper development (Bate and Rushton, 1993; Baylies *et al.*, 1995; Lawrence *et al.*, 1995; Wu *et al.*, 1995; Azpiazu *et al.*, 1996; Park *et al.*, 1996; Ranganayakulu *et al.*, 1996). Dpp signaling from the ectoderm induces development of visceral mesoderm, heart and dorsal somatic mesoderm (Staehling-Hampton *et al.*, 1994; Frasch, 1995; Baylies and Bate, 1996). (Reproduced with permission from Riechmann, V., Irion, U., Wilson, R., Grosskortenhaus, R., Leptin, M., **1997**. Control of cell fates and segmentation in the *Drosophila* mesoderm. *Development 124*, 2915–2922; © The Company of Biologists Ltd.)

Grossniklaus *et al*., 1992). Subdivision by *eve* and *slp* generates alternating domains within each embryonic segment, from which progenitors of different mesodermal tissues derive. As DNA-binding transcriptional regulators, these two molecules then induce subsequent genes associated with the determination and differentiation of cells within each of these domains. The "*eve* domain," which gives rise to the progenitors of the visceral muscles and the fat body, is characterized by the subsequent expression of *bap* and *serpent* (*srp*), respectively. The "*slp* domain" includes presumptive somatic myoblasts that will go on to express high levels of Twi, and heart progenitors that will later express genes that include *tin* (Azpiazu *et al*., 1996; Riechmann *et al*., 1997). These different mesodermal anlagen form interdependent groups of cells within the mesoderm, such that an increase or decrease in the number of progenitor cells for one tissue results in a compensatory change in the number of one or more of the other progenitors. For example, primordia of the somatic muscles that express high levels of Twi are absent in embryos lacking *slp* (Riechmann *et al*., 1997), while those of the visceral musculature are expanded in these mutants. By comparison, embryos lacking *eve* lose cells that express *bap*, and retain cells that express high levels of Twi. Although the domain of high Twi-expressing cells is not expanded in the *eve* mutant embryos, that of the *slp*-expressing cells is increased. Together, these data support the view that *eve* and *slp* play critical roles, both negative and positive, in the specification of each of these cell types (Riechmann *et al*., 1997).

The subdivision along the anteroposterior axis is also controlled, at least in part, by segment polarity genes that include *wingless* (*wg*), *hedgehog* (*hh*), and *engrailed* (*en*). All of these genes function downstream of *eve* and *slp* (Azpiazu *et al*., 1996; Riechmann *et al*., 1997; **Figure 1**). For example, the effect of *slp* on high Twi-expressing myogenic progenitors is partly due to its effect on *wg*, a Wnt family member. Wg is expressed in regions of the *slp* ectodermal domain and plays an important role in the development of the mesodermal *slp* domain (Azpiazu *et al*., 1996). Thus, in *wg* mutants, heart progenitors are absent (Lawrence *et al*., 1995; Wu *et al*., 1995; Park *et al*., 1996) as well as some somatic muscle precursors (Bate and Rushton, 1993; Volk and VijayRaghavan, 1994; Baylies *et al*., 1995; Ranganayakulu *et al*., 1996). Conversely, the *bap*-expressing progenitors of the visceral muscles are significantly expanded in *wg* mutant embryos (Azpiazu *et al*., 1996). In addition, overexpression of *wg* and components of the *wg* signaling pathway induce supernumerary heart precursors (Lawrence *et al*., 1995; Park *et al*., 1996) at the expense of the visceral mesoderm (Park *et al*., 1996).

The *hh* gene, which encodes a secreted molecule related to vertebrate Sonic hedgehog, is expressed in the ectodermal domain of Eve-expressing cells, and promotes the further development of cells within the mesodermal *eve* domain (Azpiazu *et al*., 1996). Its expression is required, but not sufficient, for formation of the visceral muscles and fat body through the induction of *bap* and *srp* expression. In a negative regulatory loop, *wg* antagonizes the action of *hh* in the *slp* domain, preventing *bap* and *srp* expression and promoting development of the heart and somatic muscles (Azpiazu *et al*., 1996). These results suggest that *wg* and *hh* are required for the maintenance of differential gene expression that is initially activated by pair-rule genes in the *eve* and *slp* domains of the mesoderm. It should be noted that, like the requirement for secreted Dpp in the dorsoventral patterning of the mesoderm described earlier, signaling molecules responsible for inductive events along the anteroposterior axis can originate in overlying ectodermal cells as well as within the mesoderm itself (Lawrence *et al*., 1994; Baylies *et al*., 1995; Lawrence *et al*., 1995; Azpiazu *et al*., 1996; Ranganayakulu *et al*., 1996), leading to the suggestion that they might play a permissive rather than an instructive role (Lawrence *et al*., 1995).

As implied in the above discussion, an important manifestation of mesoderm subdivision, specifically related to the visceral and somatic musculature, is the differential expression of Bap and Twi. Bap expression is restricted to cells that will develop as visceral musculature and Bap serves as a marker for the subsequent differentiation of these progenitors. By contrast, Twi is initially expressed uniformly throughout the mesoderm but later modulates along the anteroposterior axis such that one observes domains with high levels of expression and domains with somewhat lower levels of expression (Dunin-Borkowski *et al*., 1995). This modulation occurs in response to *wg* and *slp*, such that high levels of Twi are present in cells within the *slp* domains and low levels in cells of the *eve* domains (Dunin-Borkowski *et al*., 1995). In subsequent studies, the perdurance of high levels of Twi in the *slp* domain was shown to be essential for somatic myogenesis and prevents the formation of other mesodermal derivatives (Baylies and Bate, 1996; see Section 2.1.2.2.1).

Lastly, additional genes appear to be expressed in broad domains in the early mesoderm and may play roles in the specification and/or subdivision of the mesoderm, including *zinc finger homeodomain 1* (*zfh1*) (Lai *et al*., 1991) and the P2 transcript of *pointed* (Klambt, 1993). The actual role of each of

these proteins has not been revealed by genetic studies, since only subtle somatic muscle defects are displayed by each of these mutant embryos. However, some data suggests that *zfh1* may play a negative role in somatic myogenesis. It encodes a zinc-finger homeobox protein that is initially expressed throughout the presumptive mesoderm, but is later downregulated (Lai *et al*., 1991). It can bind to and represses transcriptional activity from E-boxes, the canonical target sites of bHLH-containing proteins. Moreover, ectopic expression of *zfh1* beyond its normal time period prevents differentiation of somatic but not visceral muscle (Postigo *et al*., 1999).

2.1.2.3. Determination of Somatic Myoblasts

Transcription factors play a critical role in activating a program of gene expression that commits cells to a myogenic program of differentiation. Some of the key factors associated with the somatic musculature are discussed below.

2.1.2.3.1. The role of the bHLH protein Twist As described earlier, the somatic mesoderm is characterized by high levels of the bHLH transcriptional regulatory protein Twi, whereas relatively lower levels of Twi are present in the progenitors of the visceral musculature and heart. Baylies and Bate (1996) demonstrated the importance of the level of Twi in determining the developmental fates of mesodermal cells by artificially modulating this level using the GAL4/UAS system. Their studies clearly demonstrated that the fate of presumptive visceral and cardiac myoblasts could be selectively altered by high levels of Twi. Changes included decreased expression of markers associated with visceral muscle fate and increased expression of muscle myosin, both characteristic features of somatic muscle fibers. While these changes suggested that high levels of Twi commit cells to a somatic muscle fate, this interpretation was more firmly established by the demonstration that ectopic expression of Twi could drive ectodermal cells into a myogenic program of differentiation (Baylies and Bate, 1996). Thus, Twi acts early in the pathway, through which myoblasts acquire the ability to express muscle-specific structural genes.

More recent studies have explored the observation that bHLH-containing proteins function as dimers, and have addressed whether Twi functions as a homodimer or acts in concert with the bHLH-containing E-protein Daughterless (Da) as a heterodimer partner. In short, these studies demonstrated that Twi homodimers function to promote a somatic muscle phenotype in mesodermal cells, while Da-Twi heterodimers actually repress this fate, presumably functioning in other mesodermal derivatives (Castanon *et al*., 2001).

2.1.2.3.2. Selection and segregation of muscle progenitors Following the segmental subdivision of the mesoderm discussed earlier, the somatic mesoderm is further divided into regions that are competent to form muscles with specific identities (Halfon *et al*., 2000). Within these competence domains, the progenitors for particular muscles will be singled out from cells that comprise an equivalence group (Carmena *et al*., 1995). This process has been best illustrated by a series of genetic experiments in which modulation of various signaling components defines sequential events for the development of a pair of dorsal embryonic muscles (reviewed in Frasch, 1999; Baylies and Michelson, 2001).

First, ectodermal signaling from both Wg and Dpp defines a region which becomes competent for dorsal muscle development (Carmena *et al*., 1998a) (**Figure 2**). The combined activities of Wg and Dpp then result in the activation of the proneural gene *lethal of scute l(1)sc* in the cells of this competence domain (Carmena *et al*., 1995; Ruiz-Gomez and Bate, 1997; Carmena *et al*., 1998a). Through a novel mechanism, the Notch protein plays a key repressive role in restricting the size of this competence domain (Rusconi and Corbin, 1998; Brennan *et al*., 1999; Rusconi and Corbin, 1999). Once determined, the localized activation of the Ras1 pathway in this domain restricts L(1)sc to a smaller cell cluster that represents the equivalence group (Carmena *et al*., 1998a). This process is mediated by Htl/DFR1 and the *Drosophila* epidermal growth factor receptor (EGFR), two receptor tyrosine kinases (RTKs) (Buff *et al*., 1998).

All cells comprising this individual L(1)sc-expressing equivalence group are initially thought to be equipotent at this stage. However, two cell types, both of them critical for somatic myogenesis, will be derived from the cells in this population. These include the muscle progenitors, which play a key role in patterning the musculature, and fusion competent cells, which are essential to the formation of multinucleate syncytia. In each L(1)sc-expressing equivalence group, a single muscle progenitor will emerge as a consequence of lateral inhibition mediated by Notch/Delta (Dl) signaling (Corbin *et al*., 1991; Bate *et al*., 1993; Carmena *et al*., 1995; Baker and Schubiger, 1996) and the activity of Argos (Aos), a diffusible inhibitor of EGFR (Carmena *et al*., 2002). L(1)sc expression will be progressively restricted to all but one cell (Carmena *et al*., 1995). This cell will go on to serve as a muscle progenitor

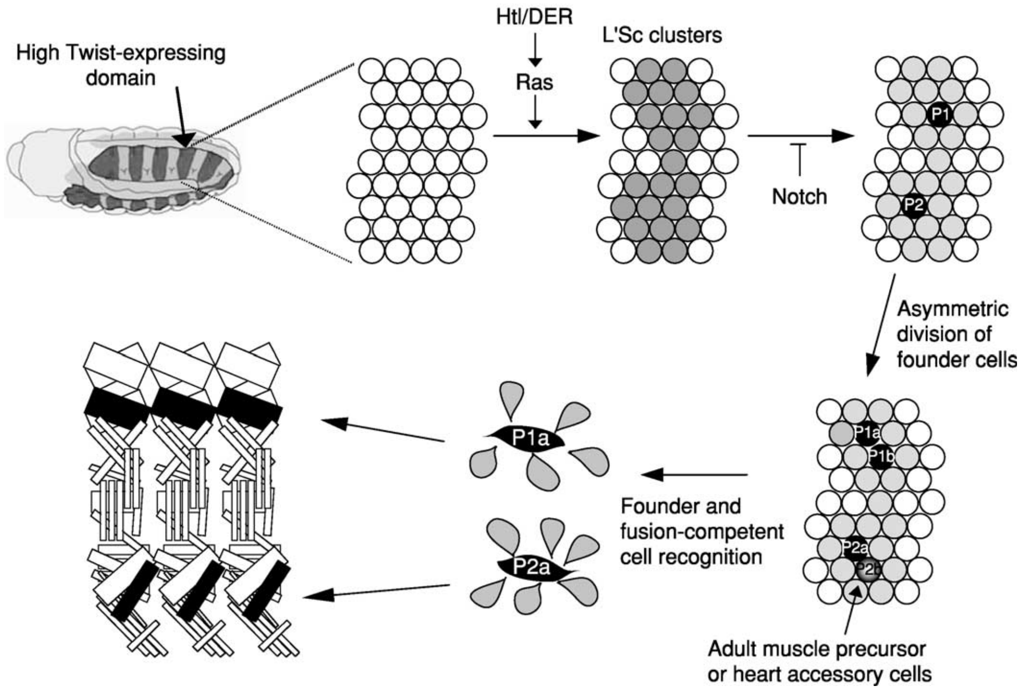

Figure 2 A schematic representation of the steps involved in *Drosophila* somatic muscle development. Twi is expressed at high (dark gray) and low (light gray) levels in segmentally repeated domains in the embryo. A variety of positional cues, in addition to localized activation of the Ras1 signaling pathway via the RTKs Htl and EGFR, result in discrete clusters of L(1)sc expressing cells in the high Twist-expressing domain. Two representative clusters are shown in gray. The process of lateral inhibition mediated by the Notch then singles out muscle progenitors (represented by P1 and P2 in black), with L(1)sc expression declining in the surrounding cells. Asymmetric division (see **Figure 3**) of the progenitor results in two founders (P1a and P1b) or a founder (P2a) and an adult muscle precursor or heart accessory cell (P2b). The other cells in the cluster become fusion-competent cells (light gray). The founder cells then fuse with surrounding fusion-competent cells to form multinucleate syncytia.

(**Figure 2**), while the rest of the cells within each group appear to become fusion-competent cells. A similar sequence of events is expected to occur in the specification of other muscle progenitors, with different combinations of signals being responsible for each equivalence group and resulting muscle progenitor. Though not actually shown for the progenitors of each muscle fiber, every equivalence group seems likely to give rise to a specific muscle progenitor with a restricted cell fate. Consistent with this hypothesis, there appear to be at least 19 distinct L(1)sc-expressing equivalence groups in each hemisegment, which arise from four regionally different cell populations within the somatic mesoderm (Carmena *et al.*, 1995). Thus, the potential exists for many distinct progenitors within the pool of equivalence groups. Of note, all muscle progenitors appear to segregate from L(1)sc-expressing equivalence groups through the action of Notch (Corbin *et al.*, 1991; Bate *et al.*, 1993; Carmena *et al.*, 1995; Baker and Schubiger, 1996). However, while many progenitors require *wg* and the activities of Htl/DFR1 and EGFR, not all of them do (Baylies *et al.*, 1995; Ranganayakulu *et al.*, 1996; Buff *et al.*, 1998; Schulz and Gajewski, 1999). Thus, perhaps a combination of signaling molecules distinguishes each equivalence group and, more importantly, the resulting muscle progenitor. Consistent with this model, the actions of Wg, Dpp and Ras have been shown to converge on a single enhancer element that integrates these positive inputs to regulate expression of the dorsal founder cell marker *eve* (Halfon *et al.*, 2000).

In contrast to the progenitor myoblasts, it is generally assumed that fusion-competent cells from different equivalence groups are all identical. Cell transplantation studies have indicated that the muscle cells are of equivalent potential and can contribute to the appropriate muscles in the region of the mesoderm into which they are tranplanted (Beer *et al.*, 1987). However, these studies examined cells approximately 8–12 min after gastrulation, which may be too early for some cell fate decisions to have been made. Thus, it seems a formal possibility that these cells may not be a homogeneous population, particularly since they arise from equivalence

groups in different regions of the mesoderm that are subjected to the influence of different signaling molecules. Future efforts may provide additional information on this topic.

After segregation of the L(1)sc-expressing muscle progenitors by various combinations of signals, each will initiate expression of a particular repertoire of nuclear proteins that mark subsets of progenitors. These proteins, the so-called muscle identity factors, play a major role in the specification and development of progenitors for each muscle fiber. This cell also divides asymmetrically to give rise to two daughters, each with a different muscle fate. The resulting founder myoblasts are the fundamental units that will then pattern the musculature, discussed in the next section.

2.1.3. Generation of Pattern in the Somatic Musculature

The somatic or body wall muscles of the *Drosophila* larva comprise a segmentally repeating pattern of 30 distinct muscle fibers per abdominal hemisegment. Each of these muscles is unique, and has properties acquired in the course of its development, through which its identity can be distinguished. These properties include size, shape, pattern of innervation, and sites of epidermal attachment. Even before such morphological distinctions are apparent, a variety of studies in the last 15 years have revealed that the pattern of muscle fibers and the identity of individual myoblasts are determined quite early in the myogenic process. This identity is established at the level of the equivalence groups and muscle progenitors described above. These cells give rise to founder myoblasts, each defined by its unique position and characteristic pattern of gene expression. The expression of particular genes provides markers for different muscle founders, and likely controls their subsequent developmental programs. Through the action of the proteins that these genes encode, founder myoblasts seed the formation of particular muscle fibers and begin to acquire features characteristic of particular muscles.

2.1.3.1. Generation of Muscle Founder Cells by Asymmetric Division

Following segregation of the muscle progenitors by a combination of signaling events, as discussed in Section 2.1.2.3 and shown in **Figure 2**, the progenitors divide to give rise to two cells with different fates. Studies following the fates of individual daughter cells have revealed six examples, in which the progenitors give rise to two sibling larval muscle founder cells (Carmena *et al*., 1995; Ruiz-Gomez and Bate, 1997; Jagla *et al*., 1998; Crozatier and Vincent, 1999). Thus, the "typical" founder cell seeds the formation of two distinct embryonic muscle fibers. Two examples have also been identified in which division of the progenitor cell gives rise to a larval founder cell and an adult muscle precursor (Carmena *et al*., 1995; Jagla *et al*., 1998). Interestingly, the adult muscle precursor maintains expression of Twi, proliferates, and goes on to form specific adult muscles (Bate *et al*., 1991; Carmena *et al*., 1995). Furthermore, one example has been found in which the progenitor gives rise to a larval founder cell and a pair of heart accessory cells (Carmena *et al*., 1998b; Park *et al*., 1998). Since the terminal fates of all daughter cells derived from progenitor cell division have not been mapped, future studies may reveal other fates for these daughter cells and provide insights into the frequency of each of the above paths.

Clearly, however, asymmetric division by muscle progenitors is a crucial step in the generation of muscle founder cells with distinct identities. In each of the progenitor cell divisions, daughter cells acquire a different cell fate as a consequence of asymmetric distribution of molecules. Insights into the identity of these molecules and possible functions in the somatic musculature came from studies on neurogenesis. Asymmetric division during development of the peripheral nervous system involves the cytoplasmic proteins Numb, Inscutable (Insc), and Prospero (Pros). In neuronal cells, Numb and Pros are provided to only one daughter cell in a mechanism that is dependent on *insc* (Rhyu *et al*., 1994; Hirata *et al*., 1995; Knoblich *et al*., 1995; Spana and Doe, 1995; Kraut and Campos-Ortega, 1996; Kraut *et al*., 1996; Spana and Doe, 1996; **Chapters 1.10, 1.11**, and **2.3**). Embryos lacking either *numb* or *insc* exhibit defects in muscle development, implicating them in the asymmetric division of muscle progenitors, shown schematically in **Figure 3** (Burchard *et al*., 1995; Uemura *et al*., 1996; Knirr *et al*., 1999). In contrast, *pros* does not appear to be expressed in the mesoderm, and mutants do not display any mesodermal defects (Broadie and Bate, 1993a). It is now clear that Numb is spatially restricted to a crescent on one side of the parent muscle progenitor, and segregates to only one daughter founder cell upon division (Ruiz-Gomez and Bate, 1997; Carmena *et al*., 1998b) (**Figure 3**). As in the nervous system, this asymmetric distribution is dependent on *insc* [previously identified as *not-enough-muscles* (*nem*); Burchard *et al*., 1995], and is localized in a reciprocal pattern to that of Numb on the opposite side of the cell (Ruiz-Gomez and Bate, 1997; Carmena *et al*., 1998b).

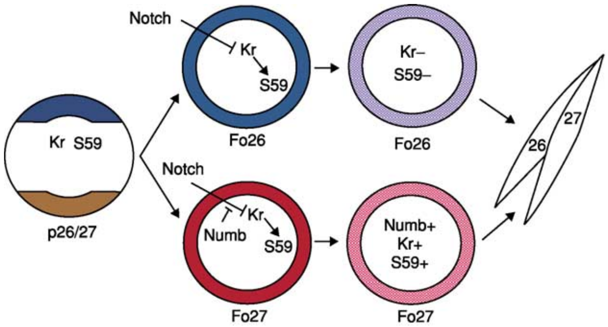

Figure 3 Sibling founder cells produced by a muscle progenitor adopt different cell fates due to asymmetric localization of cytoplasmic proteins. In this example, the progenitor to muscles 26 and 27 (p26/27) expresses the muscle identity genes *S59* and *Kr*, among others. Numb (shown in red) and Inscuteable (shown in blue) are asymmetrically distributed as crescents on opposite sides of the muscle progenitor. Upon cell division, Numb segregates only to one of the daughter cells, in which it then inhibits Notch signaling. Inactivation of the Notch pathway in this cell allows maintenance of *Kr* and *S59* expression, and defines this daughter cell as the founder to muscle 27 (f27). Activation of the Notch pathway in the sibling cell, which does not receive Numb, inhibits the expression of the muscle identity genes *Kr* and *S59*. This cell goes on in development to become the founder to muscle 26 (f26).

The *insc* gene encodes a putative cytoskeletal adaptor protein (Kraut and Campos-Ortega, 1996), and mutant embryos exhibit defects in the orientation of the mitotic spindle and localization of intrinsic factors (Burchard *et al*., 1995; Kraut *et al*., 1996; Knirr *et al*., 1997; Buescher *et al*., 1998; Jan and Jan, 1998). By comparison, *numb* encodes a membrane-associated protein that contains a PTB motif, which is essential for interaction with Notch (Uemura *et al*. 1989; Guo *et al*., 1996). As in neuronal specification, Numb inhibits the Notch signaling pathway (Frise *et al*., 1996; Ruiz-Gomez and Bate, 1997; Carmena *et al*., 1998b; **Chapters 1.10**, **1.11**, and **2.3**). The differential activation of Notch in only one daughter cell is, in turn, responsible for a different pattern of gene expression in this daughter cell. Thus, segregation of Numb switches cells from a default state, in which Notch signaling represses muscle identity genes, to an alternate state, in which the absence of Notch signaling allows the continued expression of these genes. In *insc/nem* mutant embryos, Numb fails to segregate to one side of the muscle progenitor and is distributed to both daughter founder cells (Ruiz-Gomez and Bate, 1997). Therefore, two identical muscle founder cells are present rather than two founder cells for different muscles. As a consequence, *numb* mutant embryos exhibit a defective muscle pattern, in which there is a duplication of some muscles and corresponding loss of others. A reciprocal change in the identity of the duplicated and missing muscles is observed when Numb is overexpressed (Ruiz-Gomez and Bate, 1997).

Another molecule involved in asymmetric cell division is *sanpodo* (*spdo*), which was shown to control the asymmetry of neuronal sibling fate by acting in opposition to *numb* (Dye *et al*., 1998; Skeath and Doe, 1998). Park *et al*. (1998) have demonstrated that *numb* is epistatic to both *spdo* and *Notch*. Since *spdo* encodes a tropomodulin-like protein, the authors speculate that it acts to mediate Notch signaling and transduces information from the membrane to the nucleus, possibly through association with the actin cytoskeleton.

In summary, the intrinsic factors Numb, Insc, Notch and Spdo play important roles in the generation of diversity of the larval body wall muscles, by ensuring that sibling founder cells have distinct fates. These founders go on to seed the formation of the 30 unique muscle fibers that make up the pattern of the larval musculature discussed in Section 2.1.3.2.

2.1.3.2. Grasshopper Muscle Pioneers and *Drosophila* Founder Myoblasts

Implicit in the mechanism described earlier for the segregation of founders is the notion that each founder myoblast possesses the information necessary to specify a particular muscle, and that it is able to convey this information to other cells as fusion progresses. The concept that muscle patterning might be accomplished by cells with such roles, originated with morphological studies of myogenesis in the grasshopper. Using a dye-fill approach, muscle "pioneers" were identified by their distinct morphological characteristics and behavior (Ho *et al*., 1983). These pioneers are large cells of mesodermal origin that arise early in development, when the embryonic environment is relatively simple. At this stage, the pioneers do not display features characteristic of differentiated muscles. Rather, they associate with specific sites of the ectoderm, erecting

a scaffold that delineates the territories of future muscles (Ho *et al*., 1983). Later in development, the number of nuclei in the pioneers was observed to increase, as a consequence of fusion with neighboring smaller mesodermal cells. These cells cluster around the large muscle pioneer and fuse with it to form an individual muscle (Ball and Goodman, 1985a; Xie *et al*., 1992). Most importantly, the position of every muscle in the grasshopper embryo appears to be prefigured by the presence of a mononucleate muscle pioneer in the same location (Ball and Goodman, 1985a; Ball and Goodman, 1985b; Ball *et al*., 1985b; Xie *et al*., 1992). These observations suggested that the identity of each muscle fiber might be connected to the specific features of the muscle pioneer from which it was derived.

In addition to their being morphologically distinct from the smaller mesodermal cells, the grasshopper muscle pioneers exhibit different labeling patterns with monoclonal antibodies, suggesting that these cells are also molecularly distinct (Chang *et al*., 1983; Ball *et al*., 1985a). The muscle-organizing pioneers are necessary for motor neuron growth cones to locate (or recognize) the appropriate target (Ball *et al*., 1985a). However, the most direct demonstration of their role in muscle development and muscle identity came from ablation experiments, in which the loss of a specific pioneer early in development correlated with the loss of a particular muscle fiber later. In its place, investigators observed a loose mass of small mesodermal cells that do not surround a muscle pioneer (Ball *et al*., 1985a). Thus, single pioneer cells provide an early framework for pattern formation that is retained even as the embryonic terrain becomes more complex.

The central role for muscle pioneers as pattern organizers in early muscle development seems to be a general feature of muscle assembly in arthropods and annelids (Jellies, 1990). Prior to the identification of markers for the muscle progenitors and founder cells, morphological studies suggested the presence of pioneer-like cells in the embryonic mesoderm of *D. melanogaster*. Both immunostaining with β3-tubulin and dye filling have identified segmentally repeated cells at the end of gastrulation that extend characteristic, growth cone-like processes that appeared to delineate sites of formation of future muscle fibers (Leiss *et al*., 1988; Johansen *et al*., 1989). In a methodical and thorough morphological analysis of somatic muscle formation in the *Drosophila* embryo, Bate (1990) identified distinct binucleate and trinucleate precursors in characteristic and reproducible positions as the earliest signs of muscle differentiation. All of these precursors were observed to lie exclusively in the outer layer of mesodermal cells that are in direct contact with the ectoderm. The cells immediately beneath this layer appeared to provide a population of cells that fused with the precursor and became depleted as the muscles enlarged. On the basis of these observations, Bate inferred the presence of cells reminiscent of the grasshopper pioneers that initiate the formation of bi or trinucleate precursors (Bate, 1990). These cells were termed "founder myoblasts". In contrast to the pioneers in the grasshopper, which enlarge and extend growth cones before fusion begins, muscle founders in the *Drosophila* embryo are not large enough to span the territory of the muscles they prefigure. As fusion with surrounding myoblasts proceeds, however, the syncytial precursor grows and extends growth cone-like endings toward future insertion sites on the epidermis. The remaining pool of cells that fuse with founders to form muscle precursors and mature muscle fibers was termed the "fusion-competent" population, mentioned in previous sections. Bate further proposed that the fusion-competent cells are equivalent prior to their fusion with a founder cell, but then become entrained by this founder cell to the distinct differentiation program of a unique muscle fiber (Bate, 1990). Concurrent studies corroborated the presence of distinct muscle precursors by using antisera directed against the homeodomain-containing transcription factor S59 to visualize the inferred "founder cells" (Dohrmann *et al*., 1990). In these studies, S59 expression was observed in a small subset of segmentally repeated mononucleate cells in the embryonic mesoderm that are larger than other mesodermal cells, consistent with their identification as muscle founders.

These studies imply that in *Drosophila*, as in the grasshopper, the muscle precursors and/or muscle founder cells are morphologically distinct from the fusion-competent cells, in that they are larger (Dohrmann *et al*., 1990) and extend characteristic growth cone-like processes (Leiss *et al*., 1988; Johansen *et al*., 1989). Nevertheless, these cells were observed only transiently, since fusion begins shortly after founder cell segregation. The existence of these founder myoblasts was addressed more directly using embryos, in which the process of myoblast fusion was blocked, and the muscle progenitors and founder cells were more readily observed (Rushton *et al*., 1995). This analysis utilized embryos mutant for the *myoblast city* (*mbc*) locus (Rushton *et al*., 1995; Erickson *et al*., 1997) to examine the morphology of the myoblasts late in myogenic differentiation. In the absence of fusion, the founder myoblasts were present in characteristic locations, and expressed the normal repertoire

of muscle identity genes (see Section 2.1.3.3). They appeared to differentiate as mononucleate contractile muscle fibers, with proper innervation and functional neuromuscular synapses (Rushton *et al*., 1995; Prokop *et al*., 1996). Moreover, they extended processes toward the correct muscle attachment sites. In this early study, it was concluded that the fusion-competent cells remained rounded and did not develop features associated with a mature muscle fiber, with the exception of expression of contractile proteins (Rushton *et al*., 1995). More recent phenotypic examination of *mbc* null embryos has revealed that these fusion-competent cells are actually capable of migrating to the founder myoblasts but are unable to generate syncytia (Abmayr *et al*., 2003). Thus, studies from both the grasshopper and the fruitfly indicate that the insect mesoderm is prepatterned by somatic myoblasts with distinct morphologies and individual identities, and that these pioneers or founder cells possess information associated with the identity of each particular muscle.

In the *Drosophila* embryo, segment-specific pattern of muscle precursors is apparent from their earliest emergence, prompting the question of whether homeotic genes play a role in development of segmental differences. The role of homeotic genes in the generation of pattern in the somatic musculature is discussed in Section 2.1.3.3.2 (see also **Chapter 1.8**).

2.1.3.3. Establishment of Muscle Identity

The grasshopper muscle pioneers described above are striking in that, not only do they provide a morphological illustration of the presence of two types of myoblasts, but each also has a distinct muscle-specific identity (Chang *et al*., 1983; Ball *et al*., 1985a). Indeed, features of the developing *Drosophila* musculature are reminiscent of those seen in the grasshopper, and indicate that similar cell fate decisions occur (Rushton *et al*., 1995). In this section, we turn to molecular studies describing the genes that confer and/or interpret these identities and direct unique patterns of specification or differentiation.

2.1.3.3.1. Combinatorial control of muscle identity As muscle progenitors and/or founder myoblasts segregate from the other cells of the equivalence group, they begin to express specific nuclear proteins. This unique pattern of gene expression is one of the first molecular indications, that the founder myoblasts possess distinct identities, and suggests that these identities are established at the time of cell segregation. Founder cell-specific nuclear proteins include putative transcription factors such as Nautilus (Nau) (Michelson *et al*., 1990; Paterson *et al*., 1991), S59 (Dohrmann *et al*., 1990), Apterous (Ap) (Bourgouin *et al*., 1992), Vestigial (Vg) (Williams *et al*., 1991), Muscle segment homeobox (Msh) (Lord *et al*., 1995), Ladybird (Lb) (Jagla *et al*., 1998), Kruppel (Kr) (Gaul *et al*., 1987), Eve (Frasch *et al*., 1987), and Collier (Col) (Crozatier and Vincent, 1999). Since these proteins have been useful markers for founder cells, many have been mentioned in earlier sections of this review that deal with the origins of the founder cells. We now turn to their actual roles in generating muscle diversity.

In all cases, these proteins are initially expressed in the nuclei of a subset of founder myoblasts and thereafter in all nuclei of the syncytia derived from these founders. Thus, fusion of a founder cell with surrounding fusion-competent cells results in the induction of the corresponding marker in other nuclei of the syncytium. The expression of these proteins can, in most cases, be followed into a subset of mature muscles. In one example of such a pattern of expression, staining for S59 demonstrated that its expression is turned on in the nuclei of myoblasts that fuse with the S59 expressing founder. This expression can be followed into four mature muscle fibers in each hemisegment of the embryo (Dohrmann *et al*., 1990). A second example is shown in **Figure 4**, in which Nau (Michelson *et al*., 1990; Paterson *et al*., 1991) is observed in an early embryo in the founder cell for muscle 26 [using the nomenclature of Crossley (1978) or VA1 using the nomenclature of Bate (1993)], and can later be seen in multiple nuclei within the muscle 26 (VA1) syncytium (Abmayr *et al*., 1992; Abmayr and Keller, 1998). These data suggest that information associated with distinct muscle fiber identities is contained within the founder cells and transferred to the "naïve" fusion-competent cells as they fuse with it (Dohrmann *et al*., 1990), and are consistent with the hypothesis put forth by Bate (1990) that fusion-competent cells are entrained by the founder cell to the distinct differentiation program of a unique muscle fiber.

The differential expression patterns of *nau* and the genes encoding the other proteins discussed above suggest that they act as "muscle-identity" genes and could play a pivotal role in specifying the characteristics of individual muscles. Indeed, the results of genetic studies analyzing both loss-of-function mutations and overexpression of several of these proteins are consistent with such a hypothesis. The first identified muscle identity gene, *S59*, encodes a homeodomain-containing protein that is expressed in a subset of muscles precursors and

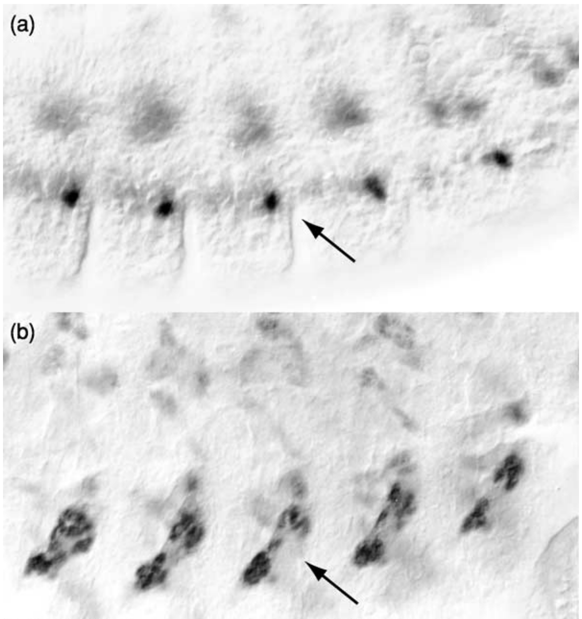

Figure 4 Fusion-competent cells take on Nau expression as they fuse with a Nau-expressing founder. Using Nau as a representative muscle identity gene, these data demonstrate that Nau is initially expressed in the nucleus of a specific founder myoblast. As multiple rounds of fusion occur, its expression can be followed in all the nuclei of the syncytia derived from this founder, supporting the model that the fusion-competent cells take on the characteristics of the founder cell with which they fuse. (a) Wild type Stage 12 embryo in which Nau expression is detected in a subset of single mesodermal muscle precursor cells. (b) Wild type Stage 15 embryo in which some cycles of fusion has occurred. As fusion progresses additional nuclei within the developing syncytia take on Nau expression. (Eds.), Current Topics in Developmental Biology. Academic Press, New York, NY, pp. 35–80; © Elsevier.)

neurons. Expression of S59 can be followed into several differentiated fibers (Dohrmann *et al.*, 1990; Carmena *et al.*, 1995), and overexpression produces alterations in the somatic muscle pattern (Knirr *et al.*, 1999). In mutant alleles of *S59*, termed *slouch* (*slou*), the development of muscles from the S59 expressing founder myoblasts is disrupted (Knirr *et al.*, 1999). The *ap* gene encodes a LIM- and homeodomain-containing protein that is also expressed in a subset of muscle precursors and neurons (Bourgouin *et al.*, 1992). Lack of *ap* function results in the loss of specific muscle fibers in the embryo, while misexpression causes muscle duplications. Kr and Lb, two homeodomain-containing proteins, are required for the formation of specific muscles, and their development is affected in embryos lacking their genes (Ruiz-Gomez and Bate, 1997; Jagla *et al.*, 1998). Conversely, Kr overexpression leads to muscle transformations (Ruiz-Gomez and Bate, 1997). Col, a COE (Col/Olf-1/EBF) transcription factor, plays a role in the formation of one specific muscle fiber (Crozatier and Vincent, 1999). Its gene is initially transcribed in the progenitors and founder cells for muscles DA3 and DO5, but expression is maintained only in the founder for DA3. While ectopic expression in the DO5 founder does not induce it to adopt a DA3 fate, *COE* mutant embryos are missing muscle DA3. Thus *COE* appears to serve as another muscle identity gene.

Msh, another homeodomain-containing protein, also marks a subset of muscle precursors (Lord *et al.*, 1995; D'Alessio and Frasch, 1996). Ectopic expression of Msh results in a disruption of the somatic muscle pattern, whereas a subset of muscles are missing in *msh* mutants (Lord *et al.*, 1995; Nose *et al.*, 1998). Interestingly, the Msh-expressing muscle progenitors and founder cells appears to segregate normally in *msh* mutants, suggesting that it is required for their subsequent differentiation (Nose *et al.*, 1998). A similar conclusion was reached in the case of Nau, the *Drosophila* MyoD homolog. In these studies, the fact that founder myoblast for muscle 3 (DA3) expresses both Nau and Vg proved to be very useful. In the same studies, embryos lacking *nau* were found to be missing a specific subset of muscle fibers, including muscle 3 (DA3) (Keller *et al.*, 1998; **Figure 5c**). Nevertheless, the founder for muscle 3 (DA3) was present, as evidenced by its expression of Vg. This cell did not differentiate into a multinucleate syncytium, however, indicating that *nau* was essential for this process. In some cases, muscles that normally express *nau* were present in the loss-of-function alleles, but their position and structure was somewhat aberrant. By comparison, ectopic expression of *nau* does not appear to affect the differentiation of muscles that normally express *nau*. Rather, the differentiation of founder myoblasts that do not normally express *nau* appears to be perturbed. These muscles are often incorrectly attached, in the wrong location, or appear to be duplications of muscles that normally express *nau*, such as muscle 5 (LO1), shown in **Figure 5d** (Keller *et al.*, 1997). Such duplications suggest that *nau* expression has altered the differentiation program of a specific muscle founder cell to an alternative plan.

It seems unlikely that a unique muscle identity gene exists for each of the 30 muscles in an abdominal hemisegment to drive each of their differentiation programs. In fact, many of these proteins are expressed in multiple, overlapping, subsets of founder myoblasts and differentiated muscle fibers. Some of these proteins may serve redundant roles

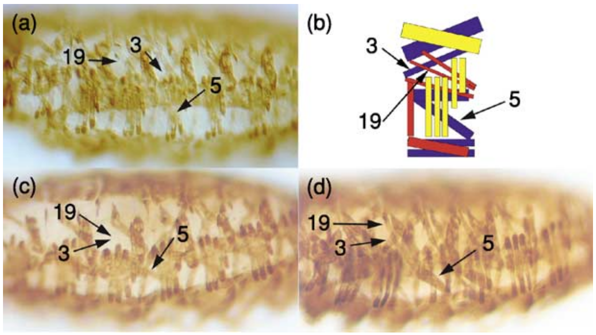

Figure 5 Loss of function and ectopic expression of muscle identity genes can alter the differentiation programs of specific subsets of somatic muscle fibers. Using the example of Nau, these data demonstrate that it plays an important role in dictating the characteristics of individual muscles. Embryos are positioned with dorsal to the top and anterior to the left. The somatic muscle pattern is visualized by immunostaining for muscle myosin. (a) Wild type embryo with somatic muscle pattern of 30 muscle fibers per hemisegment. (b) Schematic representation of a subset of the larval somatic muscle fibers. Inner, middle, and outer layers are shown in blue, red, and yellow respectively. Muscle fibers 3 and 19 have been highlighted. (c) Embryo that is mutant for *nau*. A subset of muscle fibers in the dorsolateral region of the embryo, including muscles 3 and 19, are missing. (d) Embryo in which Nau has been ectopically expressed in the mesoderm. Enlarged muscles are found in orientations reminiscent of muscle 5. (Reprinted with permission from Keller, C.A., Erickson, M.S., Abmayr, S.M., **1997**. Misexpression of *nautilus* induces myogenesis in cardioblasts and alters the pattern of somatic muscle fibers. *Dev. Biol. 181*, 197–212; and Keller, C.A., Grill, M.A., Abrnayr, S.M., **1998**. A role for *nautilus* in the differentiation of muscle precursors. *Dev. Biol. 202*, 157–171; © Elsevier.)

in subsets of the founder cells, providing alternative ways of generating a particular muscle fiber, or function in combination to specify an individual founder cell's fate. If correct, one might predict that the loss of particular genes may not necessarily result in the loss of all muscle fibers in which it is expressed. This hypothesis is consistent with the observation that mutations in many of these genes do not result in a complete absence of all fibers in which they are expressed. For example, mutations in *ap*, *nau*, and *Kr* do not affect all the muscles in which the corresponding factors are normally expressed (Bourgouin *et al*., 1992; Ruiz-Gomez *et al*., 1997; Keller *et al*., 1998). In another example, *slou* mutant embryos that lack *S59* activity exhibit various levels of disruption of muscle fibers that are derived from *S59* expressing founder cells (Knirr *et al*., 1999). These authors followed the development of three groups of muscle fibers that normally express *S59*, and found that loss of *S59* activity has different effects on individual muscle types. Loss of S59 has the strongest impact on muscles 5 (LO1) and 25 (VT1), which are absent and transformed into muscles with different identities. By comparison, absence of S59 has an intermediate effect on muscles 26 (VA1) and 27 (VA2), and only a weak effect on muscles 11 (DO3) and 18 (DT1), which are formed in *slou* mutant embryos, but with aberrant features (Knirr *et al*., 1999). Thus, muscle identity factors may function within regulatory hierarchies in each muscle, and act in a combinatorial way within these hierarchies to specify the fate of a single muscle fiber.

Studies such as those described above suggest that one or a combination of factors directs the differentiation program of a unique muscle fiber and confers on a mature muscle fiber its distinct characteristics. If such a mechanism were in place, one might anticipate that altering patterns of gene expression in muscle precursors would lead to predictable transformations in the pattern of differentiated muscles. Direct support for such a mechanism came from experiments, in which expression of a muscle identity gene characteristic of one muscle fiber was switched to that of another fiber (Ruiz-Gomez *et al*., 1997). These studies focused on a single muscle progenitor that divides to give rise to two founder cells, which form muscles 26 (VA1) and 27 (VA2). Both the muscle progenitor and, initially, the founder siblings co-express S59 and Kr. However, as development proceeds, S59 and Kr expression are lost from the founder cell for muscle 26 (VA1). By contrast, the sibling founder cell maintains expression of both genes and gives rise to muscle 27 (VA2). To analyze the role of differential *Kr* expression in the two founders, embryos that lack mesodermal Kr expression were analyzed. In these embryos, S59 expression was initiated normally in the p26/27 (VA1/2) progenitor cell, but was not maintained in the founder to muscle 27 (VA2). Consequently, muscle 27 (VA2) appears to be absent in *Kr* mutants and a muscle fiber with the characteristics of muscle 26 (VA1) is observed in its place. Conversely, expression of S59 is maintained in the founder for muscle 26 (VA1) upon ectopic expression of Kr, leading to the opposite transformation and two muscles that have the orientation of muscle 27 (VA2) (Ruiz-Gomez *et al*., 1997). This study demonstrates that Kr-mediated maintenance of expression of *S59* (and, probably, of other genes), defines specific muscle characteristics.

Other studies, on the role of these transcription factors in regulating specific programs of differentiation, suggest the existence of repressive mechanisms. For example, repression of *lb* by S59 is required in the progenitor for muscles 5 (LO1) and 25 (VT1). In *slou* mutants, which lack S59 activity, *lb* is expressed in the p5/25 (LO1/VT1) muscle progenitor, leading to a transformation of muscles 5

(LO1) and 25 (VT1) into muscles that normally express *lb* (Knirr *et al.*, 1999). A reciprocal effect is observed in embryos in which *lb* is ectopically expressed (Jagla *et al.*, 1998). Such negative interactions have also been observed between *lb* and *msh* in other progenitors (Jagla *et al.*, 1999). Finally, a regulatory role for mutual repression of identity genes has also been observed (Jagla *et al.*, 2002). In these studies, the muscle identity genes *lb*, *msh*, and *eve* act as mutual repressors. For example, presumptive *msh* muscle cells switch on *lb* or *eve* expression inappropriately in *msh* mutant embryos, indicating that *msh* normally acts as a repressor of *lb* and/or *eve* in these cells. The apparent switch in fate of the *msh*-expressing cells in *msh* mutant embryos results in the overproduction of heart cells (normally specified by *lb*) or dorsal muscles (normally specified by *eve*). By comparison, ectopic expression of *lb* represses endogenous *msh* and *eve*, leading to a re-specification of the muscle progenitors that normally express these proteins. As a consequence, an overproduction of heart cells is observed (Jagla *et al.*, 2002). In summary, reciprocal repression between transcription factors may serve as an effective mechanism to establish discrete boundaries of identity gene expression.

2.1.3.3.2. Regional muscle identity: the role of the homeotic genes Historically, loss and gain-of-function mutations in the homeotic genes were observed to cause transformation of the epidermal characteristics of one segmental unit to those of another, and mosaic analyses revealed that this effect was cell autonomous (Garcia-Bellido *et al.*, 1976). The *Drosophila* larval somatic musculature exhibits segment-specific differences from the time that the somatic muscle precursors become apparent in the mesoderm (Bate, 1990, 1993; Bate and Rushton, 1993), prompting the suggestion that homeotic genes play an autonomous role in segmental diversification of the muscle pattern. Consistent with this hypothesis, studies by Akam and Martinez-Arias (Akam *et al.*, 1985) revealed that the region of *Ultrabithorax* (*Ubx*) transcription in the embryonic mesoderm was out of register with that in the epidermis. Subsequent studies by Hooper (1986) examined the effects of homeotic mutations on the segmental pattern of larval muscle fibers. In these studies, the segmental muscle pattern of *Ubx* mutant embryos was transformed to that of more anterior segments, similar to the transformation of ectodermal derivatives. On closer examination, however, it appeared that the expression of UBx and the transformed mesodermal region were out of register in the ectoderm and mesoderm, offset by 1.5 segments (Hooper, 1986). Thus, homeotic genes are expressed in the mesoderm and regulated in a segment specific pattern, analogous to, but different from, that seen in the ectoderm. Moreover, transformations in the muscle pattern caused by homeotic mutations do not mirror the transformations seen in the epidermis. These analyses suggested an autonomous function for *Ubx* and, by extrapolation, other homeotic genes in the muscle fibers. Both *Ubx* and *abdominal-A* (*abd-A*) are expressed early in mesodermal development, before the appearance of the bi and trinucleate muscle precursors. This early expression pattern suggests that they might exert an effect on the identity of the muscle progenitors and founder myoblasts. Consistent with this hypothesis, targeted expression of Ubx and *abd-A* in the mesoderm leads to transformation of the thoracic pattern of *nau*-expressing muscle precursors and mature somatic muscles to an abdominal pattern (Michelson, 1994). The timing of expression and the effects of misexpression on muscle identity raised the possibility that the muscle identity genes discussed earlier may be targets of homeotic gene action. Indeed, such a role has been shown in regulation of the *ap* gene by Antennapedia (Antp; Capovilla *et al.*, 2001).

A notable exception to the autonomous role of homeotic genes in embryonic somatic pattern development is the second thoracic segment. In embryos that are null for *Antp*, a gene of the Antennapedia complex, the T2 and T3 somatic musculature is severely disrupted (Roy and VijayRaghavan, 1997). However, neither *Antp* nor any other known homeotic genes are expressed in the T2 mesoderm, suggesting that the observed muscle defects are due to the absence of Antp in the overlying ectoderm (Roy and VijayRaghavan, 1997). Indeed, expression of Antp exclusively in the ectoderm of *Antp* mutant embryos rescued the T2 muscle pattern, demonstrating that Antp need not be expressed in the mesoderm to influence segmental muscle pattern (Roy and VijayRaghavan, 1997). By contrast, in T3, in which Antp is normally expressed in the mesoderm, ectodermal expression is insufficient for complete rescue of the T3 muscle pattern. The authors interpret this phenotype as an indication that both ectodermal and mesodermal expression of *Antp* are required to pattern the T3 musculature. Finally, ectopic expression of Antp in the T2 mesoderm leads to a transformation of the T2 musculature to a T3-like pattern, demonstrating that these cells can be influenced by autonomous Antp. Together, these studies suggest that inductive mechanisms from the ectoderm and autonomous effects within the mesoderm influence the muscle

pattern of T2 and T3, respectively. It seems likely that a similar variety of effects of the homeotic genes on the muscle pattern of other segments is likely to be observed.

In summary, the generation of pattern in the *Drosophila* somatic musculature is not a single decision or event. It depends on a series of events involving a wide spectrum of genes that take place at different times in development to generate the complex pattern that is the larval somatic musculature. Once the pattern is crystallized, differentiation and fusion of the muscle precursors must occur to give rise to the mature larval somatic muscle pattern. This will be the subject of Section 2.1.5.

2.1.4. Determination and Differentiation of Visceral Myoblasts

The visceral, or splanchic, musculature surrounds the gut, and is responsible for contractions associated with the digestive system. The gut and overlying musculature can be divided into three different compartments that include the foregut, midgut, and hindgut. All three regions will ultimately be surrounded by circular muscles, so called because they are laid out in a network that encircles the gut (Sandborn *et al*., 1967; Goldstein and Burdette, 1971). In the midgut, a second layer of muscles is present on top of the circular muscles. These longitudinal muscles are organized into periodic linear arrays of cells that extend along the anterior–posterior axis of the gut (Campos-Ortega and Hartenstein, 1997; Georgias *et al*., 1997). In contrast to the smooth muscle of vertebrates, which serves a similar purpose to that of the insect visceral musculature, both the longitudinal and circular muscle types are striated and contain well-defined sarcomeres (Crossley, 1978). These muscles, nevertheless, have other features in common with the smooth, unstriated, musculature of vertebrates. For example, examination at the level of the electron microscope has revealed a poorly organized sarcoplasmic reticulum and transverse T tubules (Goldstein and Burdette, 1971). Additionally, while these muscles have a slow rate of contraction, they are able to contract to less than 50% of their resting length (Crossley, 1978).

The circular visceral musculature is set aside during embryonic development by the expression of *tin* and *bap*. Tin is essential for several derivatives of the dorsal mesoderm, including the circular visceral muscles, while Bap is required exclusively for these muscles (Azpiazu and Frasch, 1993; Zaffran and Frasch, 2002). Bap is a target of *tin* in the midgut (Azpiazu and Frasch, 1993; Bodmer, 1993; Yin and Frasch, 1998). It is also expressed in the precursors of the circular muscles of the foregut and hindgut, which form independently of *dpp*, and presumably the *dpp*-mediated activation of *tin* (Campos-Ortega and Hartenstein, 1997; Zaffran *et al*., 2001). Note, however, that *tin* is also a target of *twi* (Section 2.1.2.2.1), which is expressed at high levels in these cells (Baylies and Bate, 1996). The midgut circular musculature is derived from clusters of *bap*-expressing cells within the metameric repeats of the trunk mesoderm previously described, and shown in **Figure 1** (Tremml and Bienz, 1989; Azpiazu and Frasch, 1993). These cells migrate internally until they form two parallel rows of cells along the longitudinal axis. The cells then change to a more columnar shape, and become organized into a morphologically distinct layer or “palisade” (Campos-Ortega and Hartenstein, 1997). At this time, they are marked by expression of FasIII (Klapper *et al*., 2002). The cells within this layer then migrate dorsally and ventrally in a network, ultimately forming a closed tube around the gut.

In the midgut circular musculature, the combination of *tinman* (*tin*) and *bagpipe* (*bap*) influences the expression of downstream effectors of the visceral muscle differentiation program. One apparent target of these genes is *biniou* (*bin*), a member of the FoxF family of forkhead domain genes, which is activated by *dpp*, *tin*, and *bap* (Zaffran *et al*., 2001). Activation by Dpp is clearly direct, as the *bin* promoter contains a Dpp enhancer element and ectopic Dpp leads to ectopic Bin (Zaffran *et al*., 2001). Bin is expressed in both the circular and longitudinal visceral muscles, though its effect on the migration of the caudal mesoderm appears to be nonautonomous. It is necessary for the activation of differentiation genes that are expressed in the circular muscles of the trunk visceral mesoderm, including *FasIII*, *vimar*, and *brokenheart* (*bkh*) (Zaffran *et al*., 2001). Interestingly, mutation and ectopic expression of *bin* lead to reciprocal transformations between visceral and somatic muscle fates. *vimar*, another gene that is dependent on *bap* for its expression, encodes a protein with 15 tandem copies of the *armadillo* repeat (Lo and Frasch, 1998). It is expressed in both the midgut and hindgut visceral musculature slightly later than *bap*, and its expression is dependent on *bap*. The role of *vimar* in visceral muscle differentiation has yet to be defined.

The longitudinal muscles originate in the posterior region of the mesoderm, the caudal visceral mesoderm (CVM), and migrate anteriorly in two bilaterally symmetric groups of cells between the inner surface of the mesoderm and the gut (Tepass

and Hartenstein, 1994; Campos-Ortega and Hartenstein, 1997; Georgias *et al*., 1997). Ultimately, they become organized into periodic linear arrays of cells that extend longitudinally along the anterior-posterior axis of the gut. The progenitors of the longitudinal musculature are specified by a mechanism independent of that specifying the circular visceral muscles. These cells express high levels of bHLH54 (Georgias *et al*., 1997) and the homeodomain protein Zfh1 (Broihier *et al*., 1998). The bHLH54F protein was identified in a yeast two-hybrid screen for proteins that interact with the basic helix–loop–helix (bHLH) protein Daugheterless (Da). This protein is expressed transiently in the somatic mesoderm, but is expressed quite strongly in the early CVM and the migrating progenitors of the longitudinal visceral muscles. A similar pattern of expression, with respect to the visceral musculature, has been observed for *crocodile* (*croc*) and for a construct in which the *croc* promoter drives expression of β-galactosidase (Hacker *et al*., 1995). The latter construct has facilitated examination of the genetic specification of the CVM, and revealed that specification of the progenitors of the longitudinal visceral muscles is dependent on *forkhead* (*fkh*), *brachyenteron* (*byn*), and *zfh1* (Broihier *et al*., 1998; Kusch and Reuter, 1999). Of note, the circular muscles of the hindgut also originate from the caudal visceral mesoderm (Broihier *et al*., 1998; Klapper, 2000). These muscles, like the longitudinal muscles that originate in this location, are completely dependent on the presence of *brachyenteron* (Kusch and Reuter, 1999).

Another gene critical to visceral muscle development is the recently identified *jelly-belly* (*jeb*) locus, which encodes a signaling protein with an LDL receptor-repeat (Weiss *et al*., 2001). Using a yeast assay system, *jeb* was isolated in a screen for genes that were regulated transcriptionally by *tin*. As anticipated from this method of isolation, ectopic expression of *tin* results in ectopic *jeb*, indicating that *tin* is sufficient for its expression. Redundant mechanisms exist for *jeb* activation, however, since loss of *tin* has no significant impact on the presence of *jeb* transcripts. Interestingly, *jeb* is actually synthesized in the somatic mesoderm. It is expressed in the precursors of the somatic muscles of Stage 8 and Stage 9 embryos and becomes restricted to the ventral region of the somatic mesoderm by Stage 10. Jeb is then secreted and taken up by the presumptive visceral mesoderm, where it is thought to activate a signaling cascade that induces differentiation of the circular muscles. In *jeb* mutant embryos, both *myocyte enhancer factor 2* (*mef2*)-expressing and *bap*-expressing cells are clearly evident. This observation led to the conclusion that *jeb* is necessary for the differentiation, rather than specification, of visceral mesodermal precursors (Weiss *et al*., 2001; Taylor, 2002a). At the time of germ band shortening in these embryos, the *bap*-expressing precursors of the circular muscles express very reduced levels of FasIII and fail to migrate normally. It remains unclear whether the primary role of *jeb* in these cells is to direct migration, or to induce a state of differentiation that is a prerequisite for migration. Interestingly, like that described for *bin* above, the absence of *jeb* may result in a conversion of cells from visceral to somatic muscle. While experimental evidence has not definitively established that such a change occurs, the number of somatic myoblast nuclei appears to be greater than that in wild type embryos. Moreover, no significant increase in programmed cell death was observed (Weiss *et al*., 2001). If this hypothesis is correct, it is interesting that the increased number of somatic myoblasts appears to cause no defects in the somatic muscles.

An important aspect of visceral muscle differentiation that has, until recently, been unrecognized, is the ability of these cells to fuse into multinucleate syncytia before completing their differentiation program. Though numerous studies over several decades claimed that the circular and longitudinal muscles were mononucleate (Crossley, 1978; Campos-Ortega and Hartenstein, 1985; Bate, 1993; Campos-Ortega and Hartenstein, 1997), three recent studies took advantage of modern approaches and reagents to re-examine this issue. These studies revealed that the precursors of the longitudinal and hindgut circular visceral myoblasts (Klapper *et al*., 2001; San Martin and Bate, 2001) and midgut circular visceral muscles (San Martin and Bate, 2001; Klapper *et al*., 2002) are syncytial. Interestingly, these visceral myoblast fusion events utilize some of the same loci that are essential for somatic myoblast fusion (San Martin and Bate, 2001; Klapper *et al*., 2002), including *mbc* (Erickson *et al*., 1997), *sticks-and-stones* (*sns*) (Bour *et al*., 2000), and either *dumfounded/kin of irreC* (*duf/kirre*) (Ruiz-Gomez *et al*., 2000; Strunkelnberg *et al*., 2001) or *irregular-optic-chiasma-C/roughest* (*irreC/rst*) (Ruiz-Gomez *et al*., 2000; Strunkelnberg *et al*., 2001; see Section 2.1.6).

In fact, the circular muscles, like the somatic muscles discussed elsewhere in this review (see Section 2.1.6), are derived from founder and fusion-competent cells that express the cell adhesion molecules Duf (Ruiz-Gomez *et al*., 2000) and Sns (Bour *et al*., 2000) on their surface (San Martin and

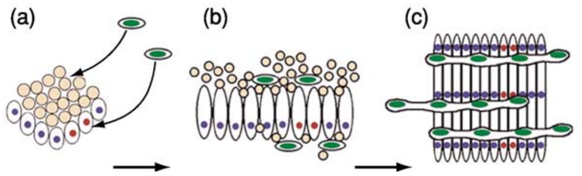

Figure 6 Diagram to illustrate the formation of longitudinal and circular visceral muscles from founders and fusion-competent cells. (a) Visceral mesoderm of late Stage 11 embryos with fusion-competent cells (orange) and associated circular founders (blue and red nuclei) together with inwardly migrating longitudinal founders (green nuclei). Local patterns of gene expression in circular founders are indicated by red and blue nuclei. (b) Stage 12 embryo showing the forming palisade of circular muscle precursors (red and blue nuclei) and associated longitudinal precursors (green nuclei) together with fusion-competent myoblasts (orange), which contribute to both kinds of muscles. (c) The completed lattice of circular and longitudinal visceral muscles, with localised patterns of gene expression as indicated. (Reprinted with permission from San Martin, B., Bate, M., **2001**. Hindgut visceral mesoderm requires an ectodermal template for normal development in *Drosophila*. *Development 128*, 233–242; © Elsevier.)

Bate, 2001; Klapper *et al.*, 2002). Examination of the founder and fusion competent cells with these markers has now revealed a clearer picture of the origins of each of visceral myoblast populations and their subsequent behavior (**Figure 6**). In short, the midgut longitudinal muscle precursors and hindgut circular muscle precursors, which are located in the posterior CVM, correspond to founder cells (Klapper *et al.*, 2001). They migrate anteriorly until they are distributed along the length of the presumptive midgut musculature and, fuse with Sns-expressing fusion competent cells (Klapper *et al.*, 2001, 2002). The midgut circular muscle founder cells, by contrast, are, essentially, the bulk of the morphologically distinct columnar cells present in the palisades of the trunk mesoderm (San Martin and Bate, 2001; Klapper *et al.*, 2002). They begin expressing β-gal driven by the enhancer trap line rP298-lacZ, which resembles Duf (Nose *et al.*, 1998) at Stage 11, and align with Sns-expressing cells. This common pool of Sns-expressing fusion-competent cells can fuse with either the longitudinal or circular founder cells, and are only loosely associated with the cells of the palisades (San Martin and Bate, 2001). These cells, not previously appreciated or described in association with the visceral musculature, are cuboidally shaped and appear to lie slightly internal to the founder cells (**Figure 6b**). Both the fusion competent cells and the circular founder cells initially express FasIII, but this expression declines in the fusion-competent cells and is detected in only the circular founder cells (San Martin and Bate, 2001; Klapper *et al.*, 2002; Chakravarti, unpublished). Fusion with Sns-expressing cells is complete by Stage 13 (Klapper *et al.*, 2002).

Interestingly, like the founder cells of the somatic musculature discussed in Section 2.1.3, the founder cells of the circular muscles do not appear to be identical, and include subsets of cells that express different founder cell markers. These markers include some of the same genes that are expressed in subsets of somatic myoblasts (San Martin and Bate, 2001), the significance of which remains to be shown. In contrast to the somatic musculature, however, only one nucleus of the syncytia, the original founder cell nucleus, expressed rP298-lacZ (Klapper *et al.*, 2002).

2.1.5. Differentiation of Founder and Fusion-Competent Somatic Myoblasts

Superimposed on or subsequent to the cell fate decisions, through which founder and fusion-competent myoblasts are specified, are the mechanisms through which these cells acquire the overt characteristics of somatic muscle. Differentiation of these cell types appears to occur in distinct steps and to be controlled by multiple gene products.

2.1.5.1. Essential Muscle-Specific Transcription Factors

In the last two decades, our understanding of the process of terminal differentiation of tissues, and the proteins that promote differentiation, has been greatly aided by the knowledge that these proteins often function as transcriptional regulators. Perhaps not surprisingly, these factors activate genes associated with a differentiated phenotype, including those that encode critical structural proteins, characteristic enzymes, and proteins that influence biosynthetic properties or morphological behavior. In this section, we discuss key transcriptional regulatory proteins that promote differentiation of somatic muscles in *Drosophila*.

2.1.5.1.1. The bHLH-containing Twist protein As described earlier, the somatic mesoderm is characterized by high levels of the bHLH transcriptional regulatory protein Twi, which acts early in the pathway, through which myoblasts acquire the ability to express muscle-specific structural genes. Studies have now shown that Twi can function as a homodimer to promote a somatic muscle phenotype in mesodermal cells. By contrast, heterodimers of Twi and the more broadly expressed bHLH protein Da can actually repress the somatic muscle fate, presumably by functioning in other mesodermal derivatives to repress the targets of Twi that promote

myogenic differentiation (Castanon *et al.*, 2001). While these results provide compelling evidence that high levels of Twi play a critical role in committing cells to a somatic muscle phenotype, the requirement for *twi* expression in mesoderm formation just a few hours earlier complicates the genetic analysis of this later role. Present studies do not specifically address whether this high level of Twi is required for the specification of both founder and fusion-competent myoblasts. In addition, studies have not addressed whether Twi might have a direct role in the transcriptional activation of genes associated with a terminal myogenic phenotype in the embryo, such as muscle myosin.

The later requirement for Twi in activating the myogenic differentiation program seems to be due at least in part to the Twi-mediated activation of *mef2* in the somatic mesoderm. *mef2* transcripts are absent in *twi* mutant embryos, and ectopic expression of Twi in ectodermal tissue induces the expression of *mef2* (Taylor *et al.*, 1995). That the effect of Twi on *mef2* is through direct transcriptional activation has been further demonstrated by the identification of a 175 bp region in the *mef2* promoter that is both necessary for *mef2* expression in the somatic mesoderm and sufficient to drive its ectopic expression in response to ectopic Twi (Cripps *et al.*, 1998). Moreover, the Twi protein binds to sequences within this enhancer (Cripps *et al.*, 1998). It is clear, however, that the sole function of high Twi is not simply to activate *mef2* in myogenic tissues. The fact that *twi* is essential for expression of Sns (B.A. Bour and S.M.A., unpublished), but *mef2* is not (Bour *et al.*, 2000), suggests the existence of other Twi targets, perhaps including such genes as *lameduck/myoblasts-incompetent/gleeful* (*lmd/minc/glee*) discussed below (see Section 2.1.5.1.2).

Another factor that suggests additional complexity in the myogenic regulatory pathway is Dmeso18E (Taylor, 2000). Its gene was identified in a rigorous subtractive hybridization-based molecular screen selecting for genes that were transcribed in wild-type 6.5–7.25 h embryos but not in embryos of the equivalent stage that were lacking *twi*. It encodes a nuclear protein with several regions of low complexity but no obvious motifs that might shed light on its function. *Dmeso18E* is expressed broadly in the mesoderm, and is observed in somatic, visceral, and cardiac cell lineages (Taylor, 2000). Expression in all of these tissues is dependent on *twi*. Intriguingly, expression is maximal in the presence of *mef2*, but is not absolutely dependent on *mef2*. This gene is therefore a potential target of *twi*, but may be modulated by *mef2* at least in the somatic musculature.

2.1.5.1.2. The GLI superfamily member lmd/minc/glee One protein responsible for complete specification and differentiation of the fusion-competent cell population is the zinc-finger containing, Gli superfamily member, Lmd/Minc/Glee (Duan *et al.*, 2001; Furlong *et al.*, 2001; Ruiz-Gomez *et al.*, 2002). Duan *et al.* identified *lmd* through their efforts to dissect the regulatory enhancer sequences of the muscle-specific transcription factor Mef2, discussed in Section 2.1.5.1.3 (Duan *et al.*, 2001). In short, these investigators utilized a *twi*-dependent *mef2* enhancer driving expression of β-galactosidase, to conduct a screen for mutations that exhibited defects in myogenic differentiation, as assayed by expression of lacZ. Their analysis revealed that embryos homozygous for mutations in *lmd* are completely lacking differentiated muscle fibers, but contain founder cells. A similar conclusion was reached by Ruiz-Gomez (Ruiz-Gomez *et al.*, 2002), who named this gene *myoblasts-incompetent* (*minc*). In both studies, the founder cells appeared to be fully differentiated, as evidenced by their expression of founder cell markers such as Kr (discussed in Section 2.1.3), and structural proteins such as muscle myosin (Duan *et al.*, 2001; Ruiz-Gomez *et al.*, 2002). These founder cells take up their normal positions, elongate, and attach to the epidermis, resulting in a muscle array reminiscent of that seen in wild type embryos. They are, nonetheless, seriously diminished in size due to the apparent lack of fusion with fusion-competent myoblasts. These observations suggested that Lmd/Minc/Glee is specifically required for determination and/or differentiation of the fusion-competent myoblasts.

Further evidence in support of this hypothesis was provided by examination of the pattern of *lmd/minc/glee* expression in Notch mutant embryos. As discussed in Section 2.1.2, Notch plays a critical role in lateral inhibition within clusters of L(1)sc-expressing myoblasts, through which founder cells are selected. In its absence, reminiscent of the interplay between neuroblasts and epidermis (Simpson, 1998), lateral inhibition does not occur and all cells take on a founder cell fate at the apparent expense of the fusion competent cells. In embryos lacking Notch, one sees a dramatic loss of Lmd/Minc/Glee-expressing cells, consistent with the model that these cells represent the diminished population of fusion-competent cells (Duan *et al.*, 2001).

As anticipated from its expression pattern in Notch mutant embryos, Lmd/Minc/Glee is expressed predominantly in the fusion-competent cells of the embryo, and is not expressed in cells coincident with founder cell markers (Duan *et al.*, 2001;

Ruiz-Gomez *et al*., 2002). Ruiz-Gomez *et al*. sought to address whether Lmd/Minc/Glee was explicitly required for specification versus differentiation of the fusion competent cells by examining expression of *twi* in these mutant embryos. In wild-type embryos, as mentioned above, expression of Twi protein is initially high in the presumptive mesoderm and declines as myoblast differentiation ensues. However, Twi persists in embryos lacking Lmd/Minc/Glee, allowing examination of the number of cells later in embryogenesis. The number of Twi-expressing cells in embryos lacking Minc was, therefore, compared to the number of Mef2-positive cells in embryos with later-acting defects in myoblast fusion. In short, the authors found much fewer *twi*-positive cells than Mef2-positive cells, suggesting that Minc is necessary for specification of fusion-competent cells, and that its absence causes a severe reduction in this population. Thus, Lmd/Minc/Glee appears to play a critical role in specification of most, if not all, of the fusion competent myoblasts, in addition to a role in their differentiation into cells that express such genes as *mef2*, *sns*, and *myosin*.

The likelihood that Lmd/Minc/Glee functions as a transcriptional regulatory protein to direct expression of genes essential for the subsequent differentiation of this population of cells, is suggested by its regulation of Mef2. Lmd/ Minc/Glee is clearly necessary for Mef2 and, either directly or indirectly, muscle myosin expression in the fusion-competent myoblasts (Duan *et al*., 2001; Ruiz-Gomez *et al*., 2002). Although Lmd/Minc/Glee does not get transported to the nucleus in all of the cells in which it is expressed, its nuclear localization is coincident with the presence of Mef2 (Duan *et al*., 2001). In addition, Lmd/Minc/Glee can activate a *mef2* enhancer that directs expression in fusion-competent cells, and sequences essential for this expression have been narrowed to a region of approximately 50 bp that binds the Lmd protein (Duan *et al*., 2001). These results demonstrate that *mef2* is a direct transcriptional target of Lmd/Minc/Glee in fusion-competent myoblasts. Other targets of Lmd are likely to include *sns*, which encodes a fusion-competent cell specific adhesion molecule (see Section 2.1.6). Expression of Sns is dependent on Lmd/Minc/Glee and is induced upon its ectopic expression (Duan *et al*., 2001; Ruiz-Gomez *et al*., 2002). While it was a formal possibility that the effect of Lmd/Minc/Glee on myogenic differentiation was solely through its induction of *mef2*, it is noteworthy that *mef2* is not essential for expression of Sns (Bour *et al*., 2000). These data suggest that Lmd/Minc/Glee must function, in part, through pathways independently of *mef2*. To test this hypothesis directly, Ruiz-Gomez *et al*. (2002) examined the ability of *mef2* to rescue the Lmd/ Minc/Glee mutant phenotype. The lack of differentiated muscle fibers in these mutant embryos indicates that Lmd/Minc/Glee is a key component of an essential myogenic regulatory pathway that functions, at least in part, independent of *mef2*.

2.1.5.1.3. The MADS box transcription factor Mef2 Mef2, the single *Drosophila* member of the Myocyte Enhancer Factor 2 (Mef2) gene family identified in vertebrates, encodes a muscle-specific MADS box (MCM1, Agamous, Deficiens, Serum Response Factor) transcription factor (Lilly *et al*., 1994; Nguyen *et al*., 1994). It is a direct target of Twi in the somatic musculature, as discussed above, and is absolutely essential for proper and complete development of somatic, cardiac, and visceral muscles (Bour *et al*., 1995; Lilly *et al*., 1995; Ranganayakulu *et al*., 1995). Embryos mutant for *mef2* are lacking differentiated, myosin-expressing cardiac cells and visceral musculature. They are also completely lacking differentiated muscle fibers. It was therefore initially compelling to consider that Mef2 might play a role, similar to that of Twi, in transcriptional regulatory mechanisms that commit cells to a myogenic program of development. However, the presence of precursors specific to the cardiac, visceral, and somatic musculature clearly indicates that these cells can be specified correctly in the absence of Mef2, and suggests a later role in differentiation. The developing mesoderm is clearly present in Stage 8 *mef2* mutant embryos, as evidenced by the pattern of cells expressing Htl/DFR1 (Lilly *et al*., 1995). Individual derivatives of this mesodermal tissue are also apparent. For example, the dorsal vessel is visible by differential interference microscopy (Bour *et al*., 1995) and expresses *tin* (Lilly *et al*., 1995). Additionally, cells committed to a visceral muscle differentiation program are present, as evidenced by expression of *FasIII* and *bap* (Lilly *et al*., 1995). Precursors of the founder myoblasts are present, as evidenced by the expression of muscle identity genes such as *nau*, *ap*, *S59*, and *eve* (Bour *et al*., 1995; Lilly *et al*., 1995; Ranganayakulu *et al*., 1995). Indeed, these marked founder cells appear to migrate correctly during germband retraction and take up their normal positions within each segment, but simply remain mononucleate and do not express proteins associated with terminal differentiation of muscle. The fusion-competent cells also appear to be specified in *mef2* mutant embryos, though the initial lack of a marker specific for this cell population prevented such an unequivocal conclusion. These myoblasts have already been specified and exhibit early signs of myogenic differentiation

that include expression of genes, such as *β3-tubulin* (Bour *et al*., 1995). While no studies have indicated that this marker is specific to the fusion-competent cell population, the mere appearance of this large number of expressing myoblasts suggested that the fusion-competent cells must be present in *mef2* mutant embryos.

In light of the above results, the major function of *mef2* in the somatic musculature appears to be to drive founder and fusion competent myoblasts to differentiate. In its absence, these myoblasts are unable to differentiate further and do not express, for example, proteins associated with the contractile apparatus such as myosin heavy chain. In fact, vertebrate Mef2 was originally identified on the basis of its ability to bind to and activate transcription from muscle specific enhancers, and a unique Mef2 recognition site in the DNA of these enhancers has been characterized. Nguyen *et al.* (1994) and Lilly (1994), have both shown that *Drosophila* Mef2 can act through this same sequence. Moreover, studies suggest that Mef2 is responsible for the activation of similar muscle-specific genes in *Drosophila*. Their products include myosin heavy chain (Bour *et al*., 1995; Lilly *et al*., 1995), α_{PS2} integrin (Ranganayakulu *et al*., 1995; Frasch and Nguyen, 1999), troponin T (Frasch and Nguyen, 1999), and muscle-specific LIM domain containing structural proteins that associate with muscle attachment sites (Stronach *et al*., 1999). The zinc finger transcription factor CF2 (Bagni *et al*., 2002) is a potential target of Mef2. This protein is first observed in developing somatic muscles at Stage 12, coincident with myoblast fusion, and later in all three muscle derivatives, somatic, visceral, and cardiac. The *muscleblind* (*mbl*) gene encodes a nuclear Cys3-His zinc finger-containing protein that participates in the organization of Z-bands and muscle attachment (Artero *et al*., 1998). Though *mbl* expression is not restricted to the musculature, it is regulated by Mef2 in these tissues. Expression of *mbl* is reduced in *mef2* mutant embryos, and ectopic Mef2 in the epidermis is sufficient to drive ectopic *mbl*. Intriguingly, Dmeso18E, a nuclear protein described above that is expressed in all three muscle types, is also dependent on Mef2 for maximal levels of transcription in the somatic musculature, but is expressed in its absence (Taylor, 2000). In the heart and visceral musculature, expression of DmesoE is completely independent of Mef2. It remains to be shown that Mef2 has a direct effect on the transcription of *Dmeso18E*, myosin heavy chain, α_{PS2} integrin and the other examples cited above, or that the expression of these genes is dependent on the presence of Mef2 binding sites.

By contrast, a requirement for Mef2 binding sites in maximal expression has been shown for the genes encoding paramyosin (Arredondo *et al*., 2001), Actin 57B (Kelly, *et al*., 2002), tropomyosin (Tm1) (Lin and Storti, 1997), and β3 tubulin (Damm *et al*., 1998). Kelly *et al*. (2002) have reported the presence of a 595 bp enhancer in *Actin 57B* that contains two essential Mef2 binding sites and is necessary for its expression in all three muscle lineages. Of note, however, this enhancer is not sufficient for maximal expression in muscle cells, nor is it responsive to ectopic Mef2. These observations led the authors to suggest the presence of additional positive and inhibitory factors that can act on this enhancer in different tissues. A similar conclusion was suggested by the analysis of *Tm1* (Lin and Storti, 1997). These authors demonstrated the presence of two enhancers in the *Tm1* gene, both of which contain Mef2 binding sites that are necessary for maximal expression. Intriguingly, these sites, like those in *Actin 57B*, are not sufficient for maximal *Tm1* expression. However, ectopic expression of Mef2 in the ectoderm does, in fact, induce *Tm1*. This result argues against inhibitory proteins in other tissues that interfere with transcription activation of these enhancers by ectopic Mef2. Rather, it favors a requirement for additional proteins that contribute to the transcriptional activation of some muscle-specific structural proteins, and suggests that some of these proteins may be present in other tissues. One potential protein involved in regulation of *Tm1* is, for example, the PAR-domain bZIP transcription factor Pdp1 (Lin *et al*., 1997b). Pdp1 is expressed in a wide variety of tissues derived from all three germ layers. It was identified, however, on the basis of its ability to interact with and activate expression of *Tm1*, and may function in collaboration with Mef2 in the regulation of this promoter. Loss-of-function alleles of *Pdp1*, however, suggest a more significant role as an essential clock gene that regulates circadian rhythm (Cyran *et al*., 2003).

A direct role for Mef2 in maximal transcription has also been suggested for the *β3-tubulin* promoter (Damm *et al*., 1998). The *β3-tubulin* gene contains an enhancer 5′ to the transcriptional initiation site that is sufficient to drive its expression in somatic myoblasts (Gasch *et al*., 1989). Critical sequences within this region are complex, but a 279 bp region containing a Mef2 consensus binding site can direct this expression (Damm *et al*., 1998). Moreover, expression driven by this sequence is completely dependent on the presence of *mef2*. Interestingly, although some discrepancy exists in the observed level of expression, β3-tubulin is clearly expressed in the somatic musculature in the absence of Mef2

(Bour *et al*., 1995; Damm *et al*., 1998). Part of this discrepancy may be a consequence of the time at which the embryos were observed. For example, the myoblasts in a *mef2* mutant embryo will ultimately be engulfed by phagocytes (Bour *et al*., 1995), a characteristic of cells that are unable to complete their differentiation program. This might account for the reduced β3-tubulin expression observed by Damm and colleagues (Damm *et al*., 1998). Additionally, it may be that β3-tubulin expression is maximal only after fusion, such that its level is lower, albeit significant, in the unfused myoblast of a *mef2* mutant embryo.

As mentioned above, ectopic expression of Mef2 in nonmuscle tissues of the embryo is capable of inducing a muscle phenotype in these tissues, including the expression of genes such as *β3-tubulin* (Damm *et al*., 1998), *Tm1* (Lin *et al*., 1997a), *nau* (Lin *et al*., 1997a), and *mbl* (Artero *et al*., 1998), but not *Actin 57B* (Kelly *et al*., 2002). In combination with results discussed above, that *nau* and β3-tubulin-expressing cells are apparent in *mef2* mutant embryos, these results appear to be inconsistent with a simple model in which Mef2 causes direct transcriptional initiation of the *nau* and *β3-tubulin* genes. Rather, the response of these genes to ectopic expression of *mef2* seems to suggest that it has committed these cells to a myogenic fate. Together, these data are consistent with several distinct mechanisms, through which *mef2* might effect myogenic gene expression. It may, for example, play an essential role in the transcriptional activation of genes such as *myosin*, for which transcripts are completely absent in *mef2* mutant embryos. It may also play an important, though more modest, role in expression of genes such as *Tm1* and *Actin 57B*, which are expressed at low levels in its absence. These data also support the existence of transcriptional regulatory proteins that have some functional redundancy with *mef2* and play a significant role in expression of genes that are not absolutely dependent on *mef2*.

In light of observations such as those described above, we suggest that *mef2* plays a primary role in the differentiation of all myoblasts, and is necessary for developing myoblasts to express proteins essential for overt characteristics of muscle. We further suggest, however, that it plays a more complex role in the expression of individual genes, with a range in which it is absolutely essential for the expression of some, and plays only a minor role in others. The recent application of microarray technology to identify genes specifically expressed in the musculature provides an enormous wealth of tools in which to address this possibility (Furlong *et al*., 2001). Interestingly, different levels of Mef2 appear to be necessary in different muscle fibers. This latter observation is derived from rescue experiments, in which it was shown that some muscle types were rescued by expression of lower levels of Mef2 while other muscles required higher levels (Gunthorpe *et al*., 1999). Thus, *mef2* may play a more diverse and complex role in myogenic differentiation than driving all cells into a simple myogenic differentiation program. *mef2* is inadequate, for example, for the complete differentiation of all myoblasts. The ability of the fusion-competent myoblasts to fuse is dependent on the cell adhesion molecule Sns (see Section 2.1.6). Sns, which serves as a marker for the fusion-competent population of myoblasts, is not dependent on *mef2* for its expression (Bour *et al*., 2000). Therefore, acquisition of a fully differentiated phenotype, in which the contractile proteins as well as fusion-associated proteins such as Sns are expressed, must invoke at least one additional protein.

Thus, both *mef2* and *lmd/minc/glee* are required for fusion-competent cells to express genes associated with overt myogenic differentiation, but only *mef2* is required in the founder cells (Taylor, 2002b). It remains to be determined whether *mef2* activation by Twi in these cells is sufficient or whether a molecule that serves a role parallel to that of Lmd/Minc/Glee is present in the founder cells. In any case, it is clear that the programs for terminal differentiation of the founder cells and the fusion-competent cells have some aspects in common, but are distinct and have important differences.

2.1.5.2. Other Aspects of Myogenic Gene Expression

In the *Drosophila* genome, a single gene encodes all of the protein isoforms of the *myosin heavy chain* gene. Hess *et al*. (1989) demonstrated that the major cis regulatory elements are located between −450 nt and 2095 nt downstream of the transcription initiation site, which includes the first two exons and intervening intron. A major level of regulation of this gene is not, however, at the level of transcription initiation but, rather, in the alternative splicing of the transcripts for different protein isoforms in different tissues and at different times (Hess and Bernstein, 1991). Zhang and Bernstein (2001) have carried out an extensive effort to correlate expression in individual muscle fibers of the embryo with utilization of particular alternatively spliced forms of the transcript. The physiological consequences of these patterns of isoform expression are now

under investigation. Presumably, the utilization of different isoforms contributes to distinct contractile activities in each muscle. Standiford *et al.* (1997, 2001) examined the sequences controlling these alternative splicing events in an effort to better understand the mechanism, through which this precise pattern is laid out, and determined that both negatively and positively acting intron sequences are present. Of the two tropomyosins expressed in muscle (Basi and Storti, 1986; Karlik and Fyrberg, 1986), *Tm1* has been the most well characterized with respect to transcriptional regulation, as described above. Though far more modest than that occurring in the myosin heavy chain gene, *Tm1* gene regulation also includes the utilization of alternative splicing to generate different protein isoforms (Basi *et al.*, 1984).

2.1.6. Myoblast Recognition and Fusion

One important aspect of myogenic differentiation in many organisms, including *D. melanogaster*, is the generation of multinucleate syncytia through the fusion of myoblasts. In vertebrates, this process cannot be initiated until the myoblasts have become competent to fuse (Abmayr *et al.*, 2003). They must then identify and adhere to their fusion partners, leading to the recruitment or activation of the fusion machinery and formation of a syncytial myotube. In *Drosophila* and the grasshopper, fusion does not occur between two equivalent myoblasts. Instead, a founder myoblast initiates the process by recruitment of a fusion-competent myoblast. Subsequent fusion events occur between the developing syncytium and more fusion-competent myoblasts, until the syncytium has attained its final cell number. In this section, we discuss molecules that have been implicated in recognition and adhesion between insect myoblasts, intracellular proteins that are essential for and promote the fusion process, and ultrastructural features at the interface of the fusing cells.

2.1.6.1. Myoblast Recognition and Adhesion

Prior to myoblast fusion in the *Drosophila* embryo, fusion-competent myoblasts must identify, migrate to, and adhere to the founder cell or developing myotube, with which they will eventually fuse. This recognition appears to be specific and directional, since founder:founder and fusion-competent:fusion-competent cell fusion has not been observed. Studies in recent years have now established that this process is driven, at least in part, by cell adhesion molecules that are expressed on the surface of myoblasts.

2.1.6.1.1. The immunoglobulin superfamily (IgSF) Genetic studies in *Drosophila* have identified three genes encoding members of the Immunoglobulin Superfamily (IgSF) that are essential for myoblast recognition and adhesion. These include *sns* (Bour *et al.*, 2000), *duf/kirre* (Ruiz-Gomez *et al.*, 2000), and *irreC/rst* (Strunkelnberg *et al.*, 2001). The *sns* locus was identified on the basis of its mutant phenotype in embryos, in which there is a complete absence of multinucleate muscle fibers and a correspondingly large number of unfused myosin-expressing myoblasts (Bour *et al.*, 2000). It is predicted to encode a protein with eight extracellular Ig domains, a single fibronectin type-III domain, a transmembrane region, and a cytoplasmic region. The *sns* transcript and protein are expressed exclusively in the fusion-competent cells of the somatic (Bour *et al.*, 2000) and visceral (San Martin and Bate, 2001; Klapper *et al.*, 2002) musculature. Sns expression is evident just prior to fusion and decreases rapidly as fusion is completed. Both biochemical and *in situ* analyses have indicated that it localizes to the plasma membrane of embryonic cells (Bour *et al.*, 2000; R. Banerjee, M. Chakravarti and S.M. Abmayr, unpublished observations). The cytoplasmic region of Sns contains potential phosphorylation sites, two proline rich regions, and stretches of homology with related proteins. The presence of these motifs may be an indication that it functions as a signaling molecule, directing events that regulate myoblast migration, recognition, and/or adhesion. This role is consistent with the mutant phenotype seen in embryos, in which the fusion-competent myoblasts do not migrate toward or adhere to the founder cells (**Figure 7**). Sns shares homology with human Nephrin, which has been implicated in the Congenital Nephrotic Syndrome (Kestila *et al.*, 1998; Lenkkeri *et al.*, 1999), *Drosophila* Hbs (Artero *et al.*, 2001; Dworak *et al.*, 2001), and a *C. elegans* transcript that has been designated C26G2.1 (S. Reynolds, W. Hanna-Rose, and S.M. Abmayr, unpublished). Of note, genetic and molecular studies have revealed that mutations in the *sns* locus (Bour *et al.*, 2000) and EMS-induced mutants in the *rolling stone* (*rost*) locus (Paululat *et al.*, 1995, 1997) are actually allelic, and map to the genetic position of *sns* (Paululat *et al.*, 1999; Bour *et al.*, 2000).

Duf was originally identified through its association with the founder cell specific enhancer trap line rP298-lacZ (Nose *et al.*, 1998; Ruiz-Gomez *et al.*, 2000; San Martin and Bate, 2001), which is expressed preferentially in the founder cells, and is not observed in the fusion competent myoblasts. It

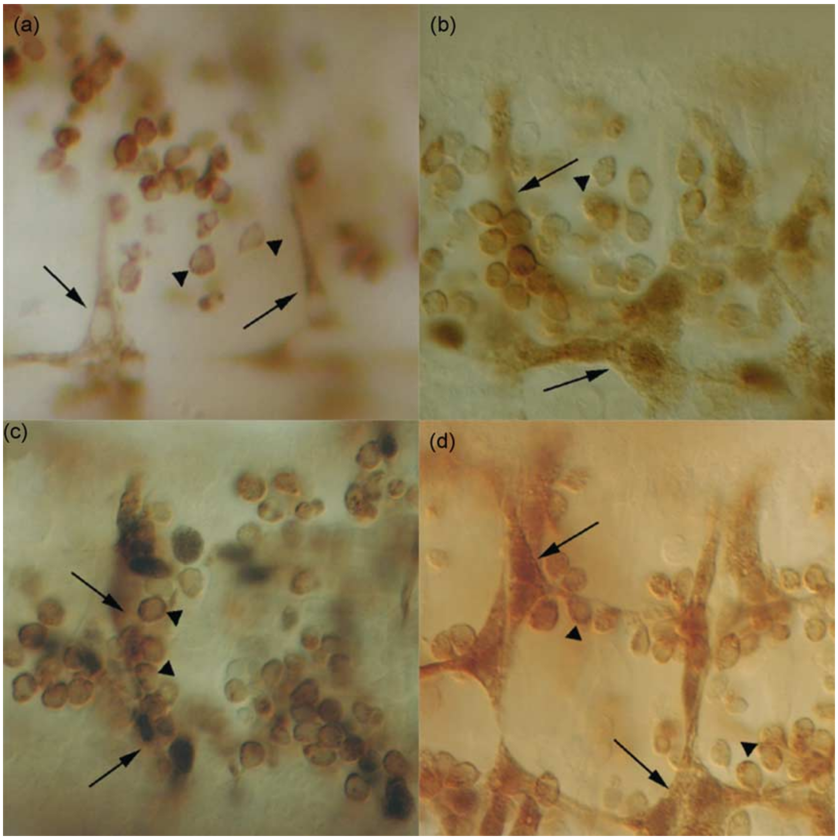

Figure 7 Stage 16 *Drosophila* embryos, in which the musculature has been visualized immunohistochemically using an antibody raised against muscle myosin heavy chain. In (b), (c), and (d), the embryos carry the *rP298lacZ* enhancer trap line, which allows identification of FO myoblast nuclei with an anti-β-galactosidase antibody. In each panel, myoblast fusion has been blocked by a different mutation. Founder (FO) myoblasts are indicated with arrows, and fusion-competent (FC) myoblasts have been indicated with arrowheads. Note that the founder myoblasts attempt to span the territory of the muscle they specify, as originally described by Rushton *et al.*, 1995. (a) Df(1)w^{67k30}/Y. This deficiency removes both the *duf/kirre* and *irreC/rst* loci. In these embryos, the FC myoblasts fail to recognize and/or migrate to their FO myoblast targets (Ruiz-Gomez *et al.*, 2000; Strunkelnberg *et al.*, 2001). (b) $sns^{Zf1.4}/sns^{Zf1.4}$. In these *sns* mutant embryos (Bour *et al.*, 2000) the FC myoblast have not migrated to their FO myoblast targets. (c) $mbc^{D11.2}/mbc^{D11.2}$. Unlike the embryos in (a) and (b), the FC myoblasts in embryos lacking *mbc* (Rushton *et al.*, 1995) can recognize and adhere to their FO targets, but do not fuse. (d) $blow^2/blow^2$. Like in (c) the FC myoblasts in a *blow* mutant embryo (Doberstein *et al.*, 1997) can recognize and adhere to their FO myoblast targets, but do not fuse.

is predicted to encode a single-pass membrane-spanning protein with five extracellular Ig domains and a cytoplasmic tail (Ruiz-Gomez *et al.*, 2000). Examination of embryos bearing a deficiency that removes *duf* and nearby genes revealed a complete absence of differentiated muscle fibers and a large number of unfused myosin-expressing myoblasts (Ruiz-Gomez *et al.*, 2000). Like what was observed in *sns* mutant embryos, the fusion competent myoblasts do not migrate or associate with founder cells in these embryos. Consistent with this deficiency phenotype, the *duf* transcript is expressed in a limited number of cells that give rise to the founder cells (Ruiz-Gomez *et al.*, 2000). It is not expressed in the fusion-competent myoblasts. This transcript remains detectable during fusion, but decreases after fusion is complete. Since *duf* was identified independently as a gene with significant homology to *irreC/rst*, and termed *kin of irreC* (*kirre*) (Strunkelnberg *et al.*, 2001), we refer to it as *duf/kirre*.

The *irreC/rst* gene, which also encodes a member of the IgSF, was originally identified on the basis of defects in axonal projection in the adult brain (Ramos *et al.*, 1993). The encoded protein is 45% similar to Duf/Kirre, and includes five extracellular Ig domains, a transmembrane region, and a highly homologous cytoplasmic tail (Ramos *et al.*, 1993; Strunkelnberg *et al.*, 2001). Interestingly, *duf/kirre* is located 127 kilobases (kb) away from *irreC/rst*. Thus, the original deficiency used to evaluate the *duf/kirre* loss-of-function phenotype also eliminated *irreC/rst* (Ruiz-Gomez *et al.*, 2000; Strunkelnberg *et al.*, 2001). Moreover, the myoblast fusion defect in these embryos can be rescued by expression of either Duf/Kirre or IrreC/Rst in the mesoderm

(Strunkelnberg *et al.*, 2001). Thus, while not originally appreciated, *duf/kirre* and *irreC/rst* actually appear to play redundant roles in the founder cells. As anticipated from this result, myoblast fusion appears to take place normally in embryos lacking only *duf/kirre*, and these embryos give rise to viable adults. While the loss of *irreC/rst* alone also gives rise to viable adults, subtle muscle defects are observed in *irreC/rst* mutant embryos. These defects include muscles that appear thin and wispy, are sometimes absent, or are present in ectopic positions (Strunkelnberg *et al.*, 2001). In comparison with *duf/kirre*, *irreC/rst* expression begins at Stage 4 and can be seen in a majority of mesodermal cells by Stage 12. Of note, IrreC/Rst is expressed in both the founder myoblasts and fusion-competent myoblasts (Strunkelnberg *et al.*, 2001). Examination of embryos mutant for *mbc*, in which myoblast fusion is blocked (Rushton *et al.*, 1995), revealed pronounced expression of IrreC/Rst in the filopodial extensions of founder myoblasts. Finally, IrreC/Rst appears to be expressed in the muscle attachment sites, or apodemes (Strunkelnberg *et al.*, 2001).

Based on their mutant phenotypes discussed above, Duf/Kirre, IrreC/Rst, and Sns all play roles in the recognition of founder cells by fusion-competent cells. Duf/Kirre and IrreC/Rst both appear to act as attractants for fusion-competent cells, since expression of either protein in the embryonic ectoderm is sufficient to target migration of fusion-competent cells (Ruiz-Gomez *et al.*, 2000; Strunkelnberg *et al.*, 2001). The fusion-competent cells in *duf/kirre* and *irreC/rst* mutant embryos do not migrate toward or adhere to the founder cells, similar to that seen in the *sns* mutants (**Figure** 7). However there is a difference in the morphology of the fusion competent cells between *irreC/rst*; *duf/kirre*, and *sns* mutant embryos. In the absence of *sns*, the fusion-competent cells remain round and do not appear to extend filopodia. In contrast, the fusion-competent cells in mutants lacking *duf/kirre* and *irreC/rst* extend filopodia, but these projections are randomly oriented (Ruiz-Gomez *et al.*, 2000). It is enticing to consider that Duf/Kirre and IrreC/Rst serve as attractants on the founder cells, and that Sns is the receptor for these attractants on the surface fusion competent cells. A similar mechanism for guidance cues being received by an IgSF member has been established in the nervous system (Kolodziej *et al.*, 1996; Bashaw and Goodman, 1999; Bashaw *et al.*, 2000). In these studies, Roundabout (Robo) and Frazzled (Fra), both IgSF members, receive extracellular signals and transmit this information to intracellular targets, leading to changes in the migratory behavior of axons (see **Chapters 1.10** and **1.11**).

A fourth IgSF member that is expressed in the developing musculature, and appears to play a role in myoblast fusion, is encoded by *hibris* (*hbs*) (Artero *et al.*, 2001; Dworak *et al.*, 2001). The *hbs* gene was identified in a screen for transcripts that were differentially expressed in founder cells versus fusion-competent cells (Artero *et al.*, 2001) and, simultaneously, through database searches for members of the IgSF in *Drosophila* (Dworak *et al.*, 2001). The Hbs protein is predicted to have eight or nine Ig domains, a fibronectin type-III domain, a transmembrane spanning region, and a cytoplasmic region. Like Sns, the cytoplasmic region contains potential phosphorylation sites, tyrosine residues that are conserved with Sns and/or Nephrin, and a candidate PEST sequence. Hbs is 29% identical and 44% similar to human Nephrin, and 48% identical and 63% similar to Sns (Artero *et al.*, 2001). It is expressed earlier in development than Sns, and in nonmuscle tissues that include the trachaea. This expression includes a subset of the fusion-competent cells but not the founder cells (Artero *et al.*, 2001; Dworak *et al.*, 2001). In cells that express both proteins, Sns and Hbs co-localize at discrete points on the cell surface (Artero *et al.*, 2001).

Surprisingly, *hbs* mutant embryos have subtle muscle defects in which muscles are missing or are smaller than normal, and exhibit only a modest increase in the number of unfused myoblasts (Artero *et al.*, 2001; Dworak *et al.*, 2001). These defects have no effect on survival, however, since these mutant embryos survive to become semi-fertile adults. They do, however, display defects in eye development, consistent with *hbs* expression in imaginal tissues (Artero *et al.*, 2001). Interestingly, overexpression of Hbs in the embryonic mesoderm results in muscle loss and an increase in the number of unfused myoblasts. This effect appears to be mediated through the cytoplasmic domain, since expression of this domain alone mimics the overexpression phenotype. Moreover, these unfused myoblasts are not observed upon ectopic expression of either a secreted or membrane bound extracellular domain (Artero *et al.*, 2001). Lastly, the mild myoblast fusion defect of *hbs* mutant embryos is dominantly suppressed by loss of one copy of *sns*, while *sns* mutations enhance the phenotype seen by overexpression of Hbs in the mesoderm. Together, these results have led to the suggestion that Hbs may function to antagonize the action of Sns (Artero *et al.*, 2001).

Consistent with the suggested roles for Duf/Kirre, IrreC/Rst, Sns, and Hbs in founder cell: fusion-competent cell recognition, these proteins are

capable of mediating adhesive events in cultured cells. Aggregation experiments in S2 cells indicate that Duf/Kirre and IrreC/Rst can mediate homotypic aggregation (Schneider *et al.*, 1995; Dworak *et al.*, 2001; M. Chakravarti, B.J. Galletta and S.M. Abmayr, unpublished data), whereas neither Sns nor Hbs alone is sufficient to induce aggregation. However, both Sns-expressing and Hbs-expressing cells can adhere to cells that express Duf/Kirre (Dworak *et al.*, 2001), and Sns-expressing cells can adhere to cells that express IrreC/Rst (Dworak and Sink, 2002; M. Chakravarti, B.J. Galletta and S.M. Abmayr, unpublished data). Together, the genetic and cell culture studies suggest that Duf/Kirre, IrreC/Rst, Hbs, and Sns play roles in fusion-competent/founder cell recognition and adhesion. Future studies will determine whether they play any role in later events essential to myoblast fusion.

2.1.6.1.2. Additional molecules that may function in myoblast recognition and adhesion Other members of the IgSF are expressed in the developing muscles and could also play a role in myoblast recognition and adhesion. These include *neuromusculin* (*nrm*), which is expressed in the cells of the peripheral nervous system, some cells of the central nervous system, and most embryonic muscle (Kania *et al.*, 1993). The expression of *nrm* in the muscles becomes evident by Stage 15 and increases during Stage 16. Embryos lacking Nrm complete embryogenesis and hatch, but die during the second instar larval stage. The CNS and PNS of these embryos have no obvious defects (Kania *et al.*, 1993). An analysis of the muscles of embryos homozygous for a *nrm* mutation has not been reported. Lastly, Nrm is able to mediate homotypic aggregation of S2 cells, as long as one mutates the amidation site that gives rise to the secreted form of the protein (Kania *et al.*, 1993). The *sidestep* (*side*) gene encodes another IgSF member that is expressed in the developing musculature coincident with myoblast fusion (Sink *et al.*, 2001). Gene *side* mutant embryos appear to have normal muscles. However, redundancy between these molecules and others could be masking a role in muscle fiber formation, as already observed for *duf/kirre* and *irreC/rst* (Strunkelnberg *et al.*, 2001).

Cadherins have been implicated in myoblast fusion by studies in vertebrate cell culture systems. However, cadherins have not been extensively studied during *Drosophila* myogenesis. *DE-cadherin*, or *shotgun* (*shg*), is a classic cadherin gene present in the *Drosophila* genome, and is expressed in embryonic epithelial tissues (Oda *et al.*, 1994; Tepass *et al.*, 1996; Uemura *et al.*, 1996). The protein is absent from mature muscles (Oda *et al.*, 1994), but its expression in pre-fusion myoblasts has not been examined. The effect of *shg* mutations on muscles has not been reported. Finally, many additional cell adhesion molecules have been identified in *Drosophila* (Hortsch and Goodman, 1991; Bunch and Brower, 1993), not including candidate genes identified through genome analysis. However, either these genes play no apparent role in myoblast fusion or this possibility has not yet been considered. Additionally, redundancy in function or a requirement earlier in embryogenesis may preclude identification of their role in myoblast fusion.

2.1.6.2. Intracellular Events Associated with Myoblast Fusion

It seems likely that recognition and adhesion between myoblasts, in turn, signals intracellular events that culminate in fusion between their plasma membranes. Thus, signaling components must be in place that effect intracellular changes and accomplish this purpose once two myoblasts have associated. One enticing possibility is that the cell surface molecules involved in recognition and adhesion may themselves initiate intracellular signaling events via their cytoplasmic tails. These may play a role in recruiting muscle-specific machinery to the sites of fusion, where subsequent membrane reorganization will take place. A second likelihood is that myoblast fusion will involve ubiquitously-expressed proteins that are associated with the reorganization of the cytoskeleton that underlies the fusing membranes.

2.1.6.2.1. Requirements for muscle-specific proteins The process of axon guidance (see also **Chapters 1.10** and **2.3**), in which the cytoplasmic tails of cell adhesion molecules regulate the actin cytoskeleton (Patel and Van Vactor, 2002), provides a useful framework, in which to consider how the cytoplasmic domains of myoblast-specific IgSF members might promote intracellular signaling. During axon guidance, the IgSF members Fra and Robo mediate attraction and repulsion, respectively. Fra has been shown to mediate attraction towards its ligand Netrin, while Robo mediates repulsive behavior of the axon in response to its ligand Slit (Bashaw and Goodman, 1999; Bashaw *et al.*, 2000; Wong *et al.*, 2001). The cytoplasmic domains of these proteins determine attractive or repulsive behavior, such that replacement of the Robo cytoplasmic domain with that of Fra converts it to mediating attraction in response to Slit. The cytoplasmic domain of Robo has also been implicated

in intracellular signaling because of its interaction with known signaling molecules including Abelson kinase (Abl), its substrate Enabled (Ena) (Bashaw *et al.*, 2000), and the novel family of Slit-Robo GTPase Activating Proteins (GAPs) (Wong *et al.*, 2001). These molecules establish a strong precedent for the potential of cytoplasmic tails of IgSF members to play a role in intracellular signaling.

In the context of myoblast fusion, IgSF members may also play a role in signal transduction via their cytoplasmic domains. This hypothesis is supported by the recent finding that the cytoplasmic domain of Duf/Kirre is capable of interacting biochemically with Antisocial (Ants)/Rolling Pebbles (Rols) (Chen and Olson, 2001). The *ants/rols* locus was identified in three independent genetic screens for genes affecting the development of the embryonic musculature (Chen and Olson, 2001; Menon and Chia, 2001; Rau *et al.*, 2001). Myoblast fusion does not occur in *ants/rols* mutant embryos. The predicted Ants/Rols protein contains several potential protein-protein interaction motifs including a RING finger, nine ankyrin repeats, three tetratricopeptide repeats (TPRs), and a coiled-coiled (Chen and Olson, 2001; Menon and Chia, 2001; Rau *et al.*, 2001). The presence of these motifs is consistent with the possibility that Ants/Rols directs protein-protein interactions that are part of a signal transduction cascade. Ants/Rols is expressed in the founder myoblasts at a time consistent with myoblast fusion. Moreover, Duf/Kirre and Ants/Rols are present on the myoblast membrane, and co-localize at points of cell–cell contact (Menon and Chia, 2001). A role for Ants/Rols as a signaling intermediate downstream of Duf/Kirre is also supported by experiments in which Ants/Rols can interact with the N-terminal region of Mbc when both proteins are expressed in *Drosophila* S2 cells (Chen and Olson, 2001). Lastly, a mouse ortholog of Ants, mants1, is expressed in the mesoderm of the mouse embryo and suggests that the function of Ants/Rols may be conserved (Chen and Olson, 2001).

In combination with data discussed in Section 2.1.6, these data are consistent with a mechanism in which the fusion-competent myoblasts migrate towards the founder myoblasts, and interact in a Duf/Kirre and Sns-dependent manner. This interaction may lead to the formation of specialized sites along the membrane at points of cell:cell contact. In founder cells, Ants/Rols could be recruited to these sites through interaction with the Duf/Kirre cytoplasmic tail. Finally, signaling molecules such as Mbc may be recruited through additional protein interaction domains, and modulate cytoskeletal structures that are critical to the fusion process. Potential targets of such a pathway are discussed in the next section.

2.1.6.2.2. Nonmuscle-specific signaling molecules: Mbc and DRac1 The *mbc* locus was originally identified through its embryonic loss-of-function phenotype, which is characterized by the absence of multinucleate muscle fibers and presence of large numbers of unfused myoblasts (Rushton *et al.*, 1995). It encodes a protein of somewhat novel structure with extensive homology to *C. elegans* Ced-5 (Wu and Horvitz, 1998), and human Dock180 (Hasegawa *et al.*, 1996). Together, these three proteins have been termed the CDM family of proteins. This protein superfamily now consists of at least 11 human proteins (Kashiwa *et al.*, 2000; Cote and Vuori, 2002; Meller *et al.*, 2002), including Dock180 and Dock2 (Hasegawa *et al.*, 1996; Nishihara, 1999), four *Drosophila* proteins (Cote and Vuori, 2002), including Mbc (Erickson *et al.*, 1997) and *Sponge* (Schejter *et al.*, 2003), three *Caenorhabditis elegans* proteins (Cote and Vuori, 2002), including Ced-5 (Wu and Horvitz, 1998), three *Dictyostelium discoideum* proteins (Cote and Vuori, 2002), one protein in *Saccharomyces cerevisiae* (Cote and Vuori, 2002), and one protein in *Arabidopsis thaliana* (Cote and Vuori, 2002; Qiu *et al.*, 2002). The most extensive studies have been done on the founding members of the CDM family, Mbc, Dock180, and Ced-5. All of these proteins contain a SH3 domain at their N-terminus, at least two proline-rich, putative SH3 binding domains at their C-terminus, and at least two additional blocks of sequence homology.

Mbc is not muscle specific, and is expressed in a wide variety of tissues in the developing embryo (Erickson *et al.*, 1997). Consequently, the defects seen in *mbc* mutant embryos are not limited to myoblast fusion, but include defects such as incomplete dorsal closure of the epidermis, abnormal fasciculation of the ventral nerve cord neurons, and severely impaired migration of border cells in the adult female ovary (Erickson *et al.*, 1997; Nolan *et al.*, 1998; Duchek *et al.*, 2001). The orthologs of Mbc that have been examined in other systems appear to be involved in diverse processes that include cell engulfment, cell migration, epithelial morphogenesis and migration, and oncogenic transformation (Hasegawa *et al.*, 1996; Wu and Horvitz, 1998). While these processes appear diverse at first glance, they all have in common the potential reorganization of the cytoskeleton. In fact, *mbc* mutant embryos exhibit perturbations in the actin cytoskeleton along the leading edge of the migrating epidermis during dorsal closure (Erickson *et al.*,

1997). As discussed in Section 2.1.6.2.1, the founder cell-specific proteins Duf/Kirre and Ants/Rols may serve as upstream activators of Mbc. Consistent with the biochemical interactions between their encoded proteins discussed above, *duf/kirre*, *rols*, and *mbc* mutants all are defective in myoblast fusion (Hasegawa *et al*., 1996; Erickson *et al*., 1997; Wu and Horvitz, 1998; Ruiz-Gomez *et al*., 2000; Chen and Olson, 2001; Menon and Chia, 2001; Rau *et al*., 2001). It is, therefore, enticing to suggest that Duf/Kirre may serve to recruit Mbc to discrete points on the membrane via Ants/Rols, leading to localized changes in the cytoskeleton. However, this model awaits *in vivo* testing.

In *Drosophila* embryonic myoblasts, localization of Mbc to the cell membrane may be mediated by interactions with the Ants/Rols protein (Chen and Olson, 2001). In other organisms and tissue types, however, the CDM proteins appear to be dependent on upstream proteins that include the small SH2-SH3 domain containing adaptor protein Crk (CT10 regulator of kinase) (Matsuda *et al*., 1996; Reddien and Horvitz, 2000). Crk has been proposed to function by linking phosphotyrosine signals at the membrane via its SH2 domain and with downstream effectors via its SH3 domain. This can lead to accumulation of Crk and its downstream effectors to discrete sites at the plasma membrane (Feller *et al*., 1998). The interaction between a CDM family member and Crk appears to be conserved in *Drosophila*. For example, *Dcrk* was identified in a Far-Western screen for proteins interacting with the C-terminus of Mbc (Galletta *et al*., 1999). Like Crk-II (Matsuda *et al*., 1994) and Ced-5 (Reichman *et al*., 1992), DCrk consists of one SH2 and two SH3 domains. Similar to that observed for Mbc (Erickson *et al*., 1997), it is expressed in a broad range of tissues during embryogenesis (Galletta *et al*., 1999). The *Dcrk* locus is located on the fourth chromosome, and a significant level of its transcripts appears to be provided to the embryos by the mother. Thus, analysis of the loss-of-function phenotype has not been straightforward. Of note, however, recent studies have demonstrated that the Crk binding sites are not essential for Mbc to function in embryos (L.B. and S.M.A., unpublished), suggesting that other proteins, perhaps including Ants/Rols, can serve the same function as Crk in bringing Mbc to the membrane.

In *Drosophila*, as in other organisms, the small GTPase Rac1 (Ras-related C3 botulinum toxin substrate) may function as a major target of the CDM family (Kiyokawa *et al*., 1998a, 1998b; Nolan *et al*., 1998; Albert *et al*., 2000; Reddien and Horvitz, 2000; Gumienny *et al*., 2001). Rac1 is a member of the Rho family of small GTPases, which are often associated with regulation of changes in the cytoskeleton. Expression of dominant negative or constitutively active forms of DRac1 in the mesoderm causes a loss of myoblast fusion (Luo *et al*., 1994), presumably by interfering with cytoskeletal events critical for myoblast fusion. More recently, loss-of-function alleles of *Drac1* and *Drac2* have been isolated and used to generated double mutants. These mutant embryos exhibit significant defects in myoblast fusion (Hakeda-Suzuki *et al*., 2002). In addition, DRac1 and Mbc have been linked genetically in the eye, in which loss of one copy of *mbc* suppresses the *Drac1* overexpression phenotype (Nolan *et al*., 1998). Studies in vertebrate cell culture systems have revealed a potential mechanism for the CDM protein influence on Rac1. The CDM proteins do not contain a consensus Dbl (diffuse B cell lymphoma)-homology region, which has been identified in previously reported guanine nucleotide exchange factors (GEFs). However, two groups have recently demonstrated an unconventional GEF activity on Rac1, via a region conserved in CDM proteins that has been termed Docker (Dock) or Dock Homology Region-2 (DHR-2) (Brugnera *et al*., 2002; Cote and Vuori, 2002). Both groups have shown that this region is capable of mediating GEF activity *in vitro*. Moreover, expression of the DHR-2 region of Dock180 is sufficient to increase the GTP loading of Rac1 in 293-T cells (Cote and Vuori, 2002). However, Brugnera *et al*. (2002) have shown that the GEF activity of Dock180 in 293-T cells is dependent on co-expression of the ELMO1 protein. ELMO1 is the vertebrate ortholog of *C. elegans* Ced-12, which was identified on the basis of a defect in the engulfment of cell corpses in *C. elegans*, and subsequently cloned (Wu and Horvitz, 1998; Chung *et al*., 2000; Gumienny *et al*., 2001; Wu *et al*., 2001; Zhou *et al*., 2001). The predicted sequences of the ELMO1 and Ced-12 proteins contain putative pleckstrin-homology domains and proline-rich regions. The *ced-12* gene acts genetically at the same step as *ced-5* (Reddien and Horvitz, 2000). Ced-12/ELMO also appears to interact physically with Ced-5/Dock180 and these proteins have been shown to cooperate in several cell culture assays (Conradt, 2001; Gumienny *et al*., 2001; Wu *et al*., 2001; Zhou *et al*., 2001). It is enticing to consider the possibility that ELMO proteins may function with CDM proteins in cellular processes.

2.1.6.3. Other Genes with Roles in Myoblast Fusion

In addition to the loci discussed above, several genes have been identified that appear to be involved in

myoblast fusion, but to which no specific biochemical role has been ascribed. The *blown fuse* (*blow*) locus was identified in a screen for lethal mutations defective in guidance of motoneurons (Doberstein *et al*., 1997). However, this defect is an indirect consequence of the lack of somatic muscles and resulting difficulties in axon targeting. Embryos lacking *blow* have no multinucleate syncytia, demonstrating that *blow* is essential for myoblast fusion. The *blow* transcript is restricted to myoblasts, and appears just prior to fusion. The predicted Blow protein, which contains no recognizable motifs or homology with proteins of known function, appears to reside in the cytoplasm (Doberstein *et al*., 1997). Two genes that have not been fully characterized also contribute to myoblast fusion. *Singles-bar* appears to encode a hydrophobic protein that is essential for myoblast fusion (Maeland *et al*., 1996). Although myoblast fusion does not occur in embryos mutant for *singles-bar*, the fusion-competent myoblasts cluster around the founder myoblasts (Ruiz-Gomez *et al*., 2000). This mutant phenotype suggests that *singles-bar* functions after cell recognition and adhesion in the myogenic program, possibly in membrane-associated events that are critical during the fusion process itself (Maeland *et al*., 1996).

The *rost* locus, mentioned previously because EMS-induced alleles of *rost* correspond to mutations in Sns (see Section 2.1.6.1), was originally identified through a P-element insertion line (Paululat *et al*., 1995, 1997). While complications in the characterization of this locus arose due to insertions in both the *rost* and *sns* loci (Paululat *et al*., 1999; Bour *et al*., 2000), it appears that the *bona fide rost* locus at cytological region 30 has defects in myoblast fusion. The transcript associated with this locus is expressed in the mesoderm, and a promoter-*lacZ* reporter that includes 400 bp upstream of the ATG is expressed in mature muscles (Paululat *et al*., 1997). The predicted Rost protein is hydrophobic and may span the membrane up to seven times. It is enriched in biochemical preparations of partially-purified membranes (Paululat *et al*., 1997), supporting its association with the membrane. While the true *rost* loss-of-function phenotype remains unclear, embryos expressing antisense *rost* exhibit a block in myoblast fusion (Paululat *et al*., 1997). In these embryos, the fusion-competent myoblasts appear to recognize and adhere to the founder myoblasts but do not fuse. This finding is supported by studies in which the P-element insertion in *rost* has been genetically separated from the P-element perturbation in *sns*, and appears to have independent effects on myoblast fusion (Paululat *et al*., 1999).

D-Titin, the *Drosophila* homolog of vertebrate Titin, serves as an elastic scaffold for both muscle sarcomeres and chromosomes (Gregorio *et al*., 1999; Trinick and Tskhovrebova, 1999; Machado and Andrew, 2000). D-Titin, a protein of approximately 2.0 mDa, is composed primarily of Ig and FnIII (fibronectin III) domains followed by a PEVK motif (Machado and Andrew, 2000; Zhang *et al*., 2000). D-Titin is expressed at a high level in myoblasts prior to fusion and appears to accumulate on the myoblast surface, often at points of contact between myoblast and myotube (Machado and Andrew, 2000; Zhang *et al*., 2000). Interestingly, it has been shown that recruitment of D-Titin to points of cell–cell contact in founder myoblasts is dependent on the Ants/Rols protein discussed above (Menon and Chia, 2001). Analysis of D-Titin mutant embryos has shown that it is essential not only for the integrity of the sarcomere, but also for myoblast fusion (Machado and Andrew, 2000; Zhang *et al*., 2000). Thus, it is possible that D-Titin is playing a role in either directly or indirectly organizing the actin cytoskeleton.

The involvement of a muscle structural protein in the myoblast fusion process is not unique to Titin. Recent studies from the Bernstein lab (Liu *et al*., 2003) have shown that paramyosin also plays a role in myoblast fusion and accumulates at discrete points in between fusing myoblasts.

2.1.6.4. Ultrastructure of the Adherent Myoblast Interface

In a detailed morphological analysis of fusing myoblasts at the level of the electron microscope, Doberstein *et al*. (1997) described a series of intracellular events that precede fusion. One first observes the appearance of clusters of electron dense vesicles on the cytoplasmic sides of opposed plasma membranes (**Figure 8**). These vesicles, which have not been observed in other cell types, appear to align with one another across the intervening membranes to form the so-called "paired vesicles" (Doberstein *et al*., 1997). After alignment, electron dense plaques are observed at the myoblast interface, on the cytoplasmic sides of the corresponding plasma membranes. The myoblasts align with each other and elongate, and fusion pores are occasionally observed adjacent to fusion plaques. Of note, fusion appears to occur at multiple sites (Doberstein *et al*., 1997), similar to that seen previously in the Lepidopteran *Antheraea polyphemus* (Stocker, 1974). Thus, it does not appear that myoblast fusion in *Drosophila* utilizes a simple zipper mechanism that originates from a single site. The fusion process is completed as the membrane vesiculates and is

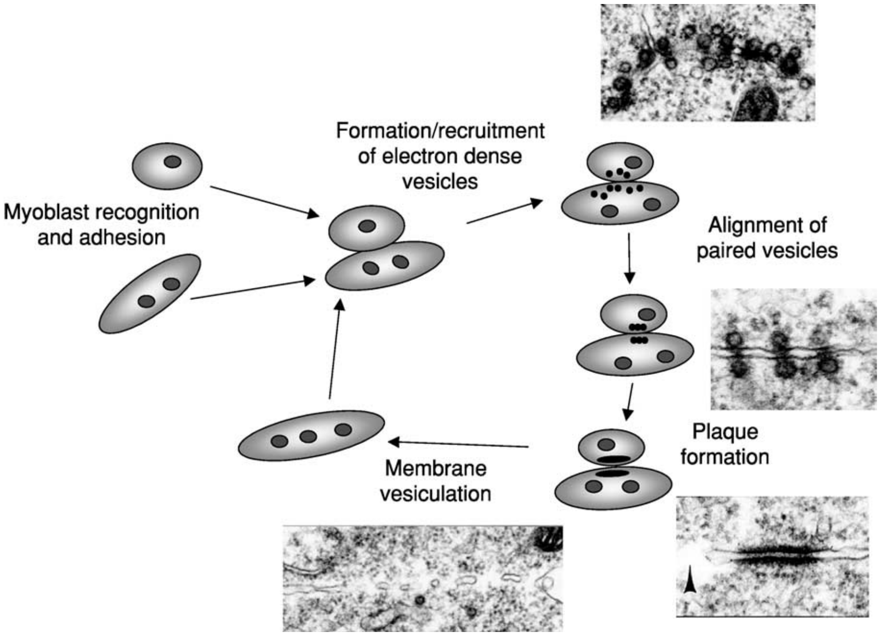

Figure 8 A schematic representation of the ultrastructure of the interface of fusing myoblasts in *Drosophila*, with corresponding electron micrographs. First, myoblasts must recognize and adhere to each other (upper left). Electron dense vesicles are then observed on both sides of the opposing plasma membranes (top). These vesicles subsequently align with each other across the plasma membranes (upper right) and form a structure, which has been termed the prefusion complex. Next, electron dense plaques are observed just under the opposing plasma membranes (lower left). Finally, the membranes vesiculate leading to cytoplasmic continuity (bottom). (Reproduced from Doberstein, S.K., Fetter, R.D., Mehta, A.Y., Goodman, C.S., **1997**. Genetic analysis of myoblast fusion: *blown fuse* is required for progression beyond the prefusion complex. *J. Cell Biol. 136*, 1249–1261; by copyright permission of The Rockefeller University Press.)

removed. Figure 8 diagrams the proposed steps of myoblast fusion and shows electron micrographs collected by Doberstein *et al.* (1997).

In an effort to extend the study of these ultrastructural features of myoblast fusion, similar morphological studies were carried out using embryos mutant for several of the loci discussed in this section. These embryos were examined at the ultrastructural level to determine the point at which the fusion process was arrested. In *blow* mutant embryos, for example, the vesicles accumulate in prefusion complexes, but no electron dense plaques are observed. Assuming that the electron dense plaques are formed from an association between vesicles and the plasma membrane, it is possible that the cytoplasmic Blow protein is involved in initiating or mediating this step. The EMS-induced *rost*^{15} mutation, which is actually allelic to *sns*, was also examined at the ultrastructural level. Surprisingly, fusion is arrested at a fairly late stage in these mutant embryos, since electron dense plaques accumulate but the plasma membrane does not break down. Recall, as discussed earlier in Section 2.1.6, that the founder and fusion-competent myoblasts do not recognize or adhere to one another in *sns* mutant embryos (Figure 7). However, since the sequence lesion in *rost*^{15} has not yet been identified, it is possible that it is a hypomorphic mutation and that some of the Sns protein is still functional. Support for this possibility is provided by the mutant phenotype of *rost*^{15} mutant embryos (Paululat *et al.*, 1995), in which myoblast fusion does not appear to be completely blocked. Few prefusion complexes were apparent in embryos lacking Mbc, suggesting that this protein may play an early role in vesicle accumulation. It is possible, for example, that Mbc-induced changes in the actin cytoskeleton are required for the recruitment of the electron dense vesicles.

Two additional genes that affect myoblast fusion have been examined at the ultrastructural level. In a separate analysis, embryos mutant for the *rost* locus were examined, and small syncytia containing 2–4 nuclei were observed (Rau *et al.*, 2001). However, fusion did not proceed further, and no prefusion complexes or electron dense plaques were observed. Finally, Doberstein (Doberstein *et al.*, 1997) also examined the ultrastructure of fusing myoblasts in embryos, in which a constitutively active form of the small GTPase Rac1 had been expressed. These embryos have prefusion complexes, electron dense vesicles, and isolated fusion pores. The plasma membranes of the myoblasts come in close apposition but do not appear to vesiculate. For these

reasons, constitutively active Rac1 is believed to block myoblast fusion at a relatively late step.

2.1.7. Maturation of Muscle Fibers

Muscle differentiation and maturation involves three critical processes: formation of the contractile apparatus, attachment of the muscle to the epidermis, and formation of neuromuscular junctions (NMJs) that control the muscle contractions (see also **Chapters 2.2** and **2.3**). These three processes are essential for the generation of force by the muscle, exertion of this force onto the body skeleton, and regulation of this force through neural connections. The contractile apparatus has been described in some detail elsewhere (Bernstein *et al*., 1993). Herein we briefly describe some aspects of muscle attachment and innervation (see also **Chapters 1.10** and **2.3**).

2.1.7.1. Epidermal Attachment

Following the earliest fusion events, the developing myotubes extend growth cone-like filopodia that migrate over the epidermis. Projections on both ends of the muscle will seek out and contact attachments sites, or apodemes, on the surface of the Epidermal Muscle Attachment (EMA) cells (Bate, 1990; Volk, 1999). These attachments must withstand the forces associated with muscle contraction. They must also, like axon guidance, assemble in a carefully orchestrated pattern.

The EMA cells are a specialized class of epidermal cells associated with muscle attachment, and some of the earliest-acting molecules required for muscle attachment are proteins that influence the differentiation program of these cells. Recent studies demonstrate that positioning of these cells is achieved through repression of the *hh* pathway through *wg* signaling at the parasegment boundary (Piepenburg *et al*., 2000). Molecules that are specifically expressed in and control differentiation of the EMA cells include Stripe (Sr), an EGR (erythrocyte growth factor receptor)-like nuclear protein that contains zinc-finger motifs and may function as a transcription factor (Lee *et al*., 1995; Frommer *et al*., 1996). Embryos homozygous for a severe mutant allele of *stripe* exhibit an aberrant somatic muscle pattern, in which the myotubes often send filopodia in incorrect directions. In late stages of embryonic development, most of the myotubes are randomly scattered, do not attach to the epidermis, and fusion is blocked (Frommer *et al*., 1996). Interestingly, ectopic expression of Stripe in other epidermal cells causes them to differentiation as muscle attachment cells and to serve as attractants for somatic myotubes (Becker *et al*., 1997; Vorbruggen *et al*., 1997).

Mutations in segment-polarity genes that cause an absence or ectopic appearance of these cells also result in disorganized muscle fibers, suggesting that the EMA cells normally guide migrating muscles to their attachment sites (Volk and VijayRaghavan, 1994). The *delilah* (*dei*) gene, which encodes a bHLH containing transcription factor (Armand *et al*., 1994), has the potential to play a role in the differentiation of these cells. The *Drosophila* epidermal growth factor receptor DER is required for the final differentiation of EMA cells and strengthening of muscle attachment, and the *Drosophila* neuregulin homolog Vein is thought to be the ligand of DER (Yarnitzky and Volk, 1995). Inductive interactions between the myotube and the attachment cells are mediated by *vein* (Yarnitzky *et al*., 1997).

Additional genes that are expressed in the EMA cells include attachment-site specific markers such as *groovin* (Volk and VijayRaghavan, 1994), *alien* (Goubeaud *et al*., 1996), and β_1*-tubulin* (Buttgereit *et al*., 1991). Transcription of β_1*-tubulin* is actually dependent on muscle insertion (Buttgereit, 1996). The *masquerade* (*mas*) gene encodes a secreted molecule that is expressed in the epidermis (Murugasu-Oei *et al*., 1995). It has the potential to function as a serine protease, though no protease activity has been detected. Embryos mutant for *masquerade* exhibit defects in muscle attachment, suggesting that its role is to stabilize this interaction. Examples of other genes that are expressed at muscle attachment sites include those encoding the *Drosophila* Sema5C (Bahri *et al*., 2001), a cell-surface glycoprotein, and Hbs, an IgSF member described in Section 2.1.6.1.1 (Artero *et al*., 2001). While no Sns protein has been detected at attachment sites, it is intriguing that its mRNA appears to be present in these cells (Bour *et al*., 2000). Phenotypic analysis of mutations in these genes has not revealed a role in the formation of epidermal attachment sites, though it remains a formal possibility that muscle attachment involves redundant mechanisms.

On the muscle side, the spectrin-related molecule Msp-300, which is expressed at the leading edge of migrating muscles, appears to play a role in the migration of the filopodia (Volk, 1992), and Msp-300 loss-of-function mutants exhibit defects in the ability of the myotube to extend toward its attachment site. This effect is amplified in genetic combination with mutations in *laminin* (Rosenberg-Hasson *et al*., 1996), suggesting an involvement of the extracellular matrix. M-spondin is among the extracellular matrix (ECM) molecules that is expressed in the developing muscle (Umemiya *et al*., 1997).

Once attachment has occurred, one remaining step in this process is to strengthen the attachments, allowing them to withstand the forces of contraction. This step includes the association of cell surface receptors specific to both the myotube and the ectoderm, and occurs rather late in the myogenic differentiation program. The position-specific integrin proteins $\alpha_{PS1}\beta_{PS}$ and $\alpha_{PS2}\beta_{PS}$ play a key role in this aspect of muscle attachment. Whereas β_{PS} is expressed on both cell types, α_{PS1} and α_{PS2} are expressed in complementary patterns in the EMA cell membrane and muscle cell membrane, respectively (Brown, 1994). These complexes play a general role in mediating interactions between the muscle and the overlying epidermis. At Stage 16, embryos bearing mutations in the β_{PS} subunit gene, *lethal myospheroid* (*l(1)mys*), contain multinucleate syncytia that appear to form normally. By Stage 17, however, the body wall muscles appear to begin detaching from the epidermis as a consequence of contraction, and this becomes pronounced after hatching. Although they remain attached for a slightly longer time, the muscles of embryos mutant for the α_{PS2} subunit gene, *inflated*, exhibit a similar mutant phenotype (Bogaert *et al*., 1987; Brown, 1994). Tiggrin, the ligand for the α_{PS2} integrin, is required for proper muscle function as well (Bunch *et al*., 1998). These proteins, then, appear to function as anchors to stabilize and strengthen the muscle-apodeme interaction against the forces of contraction. However, the delayed response of the muscles to the absence of the α_{PS2} subunit suggests the possible contribution of other molecules to a strong attachment site. One structural protein that plays a role in the integrity of muscle attachment is β_1-tubulin. It is expressed at the apodemes, possibly to provide a rigid structure that will withstand the tensile forces of muscle contraction (Buttgereit *et al*., 1991).

Like extending axons in the nervous system, mechanisms must be in place to direct myotube elongation to the correct location. One might expect molecules associated with membrane extensions and filopodia formation to play a major role in the ability of the muscles to physically contact their attachment sites. This targeting depends on the EMA cells (Volk and VijayRaghavan, 1994), which may provide guidance cues or attractants that direct migration. The EMA cells may also provide specific recognition molecules associated with precise attachment. The accuracy of attachment is also likely to depend on molecules specific to the muscle fiber that control its precise site of insertion. The sites utilized by the myotube in order to accomplish this purpose, seem destined to be intimately associated with the identity of the muscle fiber itself, and the specific differentiation program controlled by the founder cell, from which the muscle derived. At present, the mechanisms by which differentiated myotubes identify the correct place to insert into the apodemes, or epidermal muscle attachment sites, are not clear (Volk, 1999).

Nevertheless, we have some early hints. Interestingly, the Derailed (Drl) protein is expressed on a small number of muscles and tendon cells (Callahan *et al*., 1996). In *derailed* mutants, these particular muscles fail to elongate or elongate improperly, consistent with the notion that Derailed plays a role in the precise recognition pattern that is achieved. The fact that *derailed* encodes a receptor tyrosine kinase suggests that signaling events between these two germ layers may be occurring. Possibly, this is an early indication that signaling mechanisms reminiscent of those in axon guidance may come into play in this process.

2.1.7.2. Motor Neuron Innervation

Formation of synapses between motoneurons and the muscles that they control begins after the muscle pattern is crystallized, midway through embryogenesis (see also **Chapter 2.3**). Using retrograde dye labeling in embryos at about 13 h after egg laying, two groups examined the behavior of the motoneurons during muscle contact. They demonstrated that filopodia extend from individual motoneurons to contact multiple muscle fibers (Halpern *et al*., 1991; Sink and Whittington, 1991). Ultimately these filopodia retract from adjacent muscles and undergo stereotypical branching to maximize contacts on a single muscle fiber. Confocal time lapse imaging demonstrated that the filopodia are highly dynamic, as they appear to scan along the surface of the muscle fibers (Keshishian, 1993; Keshishian and Chiba, 1993).

One of the most significant advances in our understanding of muscle innervation in the last decade is the role of the muscle cells in this process. In the mid 1980s, Lawrence and colleagues took advantage of the observation that the muscle pattern of the *Drosophila* adult differed between males and females in one segment, to examine the role of innervation in dictating muscle pattern. A now classic set of experiments utilized genetic mosaics to ask which cells controlled the development of this male-specific muscle (Lawrence and Johnston, 1984; Lawrence and Johnston, 1986), and revealed that the determinative cells did not contribute to the muscle itself and were not myoblasts. Rather, the authors suggested that the sex and segmental identity of this muscle was controlled by the neuron

that innervated it. In contrast to the hypothesis put forward by these studies, however, it is clear that motoneuron innervation does not contribute to the patterning of the larval body wall muscles. Indeed, as elaborated in Section 2.1.3, the pattern of muscle fibers is dictated by the presence of single founder cells that seed the fusion process and are specified hours before innervation occurs. Broadie and Bate sought to address this issue directly, and examined muscle development in embryos in which motoneuron development is delayed (Broadie and Bate, 1993b). Their observations revealed that, in the absence of motor nerves, myoblasts can fuse normally, form proper attachments, and develop the electrical properties of larval muscles in a normal time course. Thus, innervation appears to play no role in patterning, morphogenesis, maintenance, or physiological development of the somatic muscles in the *Drosophila* embryo (Broadie and Bate, 1993b).

By contrast, numerous studies have addressed the role of the muscle cells in the neuromuscular junction. Embryos mutant for the *twi* gene and completely lacking mesoderm, still exhibit morphologically normal presynaptic zones (Prokop *et al.*, 1996). However, the motor axons fail to defasciculate from the neuronal bundles and do not branch (Landgraf *et al.*, 1999). Embryos mutant for *mef2*, in which the myoblasts fail to differentiate, also form active presynaptic zones. In this case, the zones fail to localize at neuromuscular contacts, indicating that a *mef2*-dependent step in differentiation is necessary (Prokop *et al.*, 1996). Interestingly, a single differentiated founder cell is sufficient to provide the cue for branching morphogenesis (Landgraf *et al.*, 1999). Moreover, neither defasciculation nor axon targeting are dependent on myoblast fusion, since motoneurons of embryos mutant for *mbc* exhibit functional neuromuscular synapses (Prokop *et al.*, 1996).

Although the initial targeting of the motoneuron is broader than the final pattern of contact sites, the precision with which this pattern is achieved suggests underlying forms of recognition. Indeed, experimental studies have addressed the plasticity of motoneuron targeting by deleting or duplicating specific muscle fibers. These studies revealed that *Drosophila* motoneurons can distinguish between individual muscle fibers, and that this recognition is mediated by the growth cones (Cash *et al.*, 1992; Keshishian *et al.*, 1993). Only limited information is available, however, concerning the exact molecular mechanisms governing pathfinding and synaptic recognition. A genetic screen, designed to identify loci associated with motoneuron pathfinding and targeting, uncovered several loci, including *beaten path*, *stranded*, *short stop*, *walkabout*, and *clueless* (Van Vactor *et al.*, 1993). Not surprisingly, candidates for target recognition also include adhesion molecules that are expressed on the surface of muscle fibers and at synapses. Fasciclin III, a cell adhesion molecule in the immunoglobulin superfamily, is expressed on motoneuron RP3 and its synaptic targets, the ventral longitudinal muscles 6 and 7 (Chiba *et al.*, 1995). Similarly connectin and Toll, two cell surface glycoproteins of the leucine-rich repeat family, are expressed on a subset of neurons and the muscle fibers that they innervate (Nose *et al.*, 1992; Halfon *et al.*, 1995). The loss of one or both alleles of *Toll* results in widespread defects in muscle pattern and motoneuron number (Halfon *et al.*, 1995). In some cases, these molecules can mediate adhesion between cells in culture. Semaphorin II, a secreted protein, is expressed transiently in a single large muscle during the time of motoneuron outgrowth and synapse formation (Matthes *et al.*, 1995). Of note, mutations in several of these genes do not have significant effects on neuromuscular connections, suggesting either that the appropriate molecules have not yet been identified or, more likely, that formation of correct synaptic connections is ensured by redundancy. In either case, our understanding of how the elaborate pattern of muscle innervation by motoneurons is accomplished is only in its early stages.

2.1.8. Concluding Remarks

The last decade or so of the 20th century yielded remarkable advances in our understanding of myogenesis in the *Drosophila* embryo. Many of these advances have been made possible by new technologies that pair molecular biology with genetics or cell biology, and include *in situ* hybridization, confocal microscopy, large-scale genome-wide genetic screens, and the availability of the *D. melanogaster* genome sequence, to name a few. Indeed, progress is occuring at such a rapid pace that additional information is likely to be forthcoming as this review goes to press. The approaches that have been developed and information that is now available hold promise for the 21st century in continuing this rapid pace. Among the issues to be investigated are the combinatorial pathways, through which muscle identity genes act, the molecular details of fusion-competent cell specification, the mechanism by which the extent of fusion and resulting muscle size are determined, and the molecules regulating the specificity of muscle attachment. The next two decades have the potential to be quite exciting.

Appendix

Genes discussed in this review that have an impact on embryonic myogenesis. Some of these genes play a global role in cell fate specification, and are discussed elsewhere in this volume. Others may be expressed in nonmuscle tissues, but affect muscle development. Finally, the majority of these genes are expressed within muscle tissues and affect their specification, differentiation or function.

Appendix

Name	*Abbr.*	*Structure and/or apparent function of encoded protein*
Actin 57B	*Act57B*	Component of muscle sarcomere
alien		Nuclear corepressor of the hormone receptor superfamily
Antennapedia	*Antp*	Homeotic gene; homeodomain containing protein; controls segmental identity of muscle pattern
antisocial (*rols*)	*ants*	Ring Finger, Ankyrin repeat, TPR, coiled coil containing cytoplasmic protein; founder cell specific signaling that is essential for myoblast fusion
apterous	*ap*	LIM homeodomain containing protein; muscle identity gene
argos	*aos*	Diffusible inhibitor of DER
β3-tubulin		Expressed in somatic and visceral muscle
bagpipe	*bap*	Homeodomain encoding gene; subdivides mesoderm; essential for visceral mesoderm
beaten path	*beat*	Novel secreted protein that regulates defasciculation at motor axon choice points
bHLH54		bHLH containing protein
biniou	*bin*	FoxF family of forkhead domain containing proteins involved in visceral mesoderm development and midgut morphogenesis
blown fuse	*blow*	Novel cytoplasmic protein; essential for myoblast fusion
brachyenteron	*byn*	Involved in early specification and features of the caudal visceral mesoderm (CVM)
brokenhearted	*bkh*	Encodes the alpha subunit of the Go protein, involved in specification of precursor cells of the heart tube, the visceral muscles, and the nervous system
CF2		Zinc finger containing transcription factor
clueless (abrupt)	*ab*	Zinc finger transcription factor; myogenic marker downstream of Mef2
collier	*col*	COE transcription factor family member; muscle identity gene
Connectin	*Con*	Cell surface glycoprotein involved in neuromuscular junctions
crk		SH2-SH3 containing adapter protein
crocodile	*croc*	Fork head domain protein required for head structures
daughterless	*da*	bHLH containing E protein
decapentaplegic	*dpp*	TGFβ family member; signaling associated with subdivision of the mesoderm
delilah	*dei*	bHLH containing nuclear protein expressed in muscle attachment sites
derailed	*drl*	Axon guidance receptor
dorsal	*dl*	NF-κB related transcription factor; required for specifying D/V axi
Drac1		Small monomeric GTPase; essential for myoblast fusion
dumfounded (kirre)	*duf*	Ig Superfamily transmembrane protein expressed in muscle founders
egfr		Epidermal growth factor receptor
engrailed	*en*	Homeodomain containinging protein; muscle identity gene
even-skipped	*eve*	Homeodomain-containing pair-rule gene; muscle identity gene
Fasciclin 3	*Fas3*	Ig Superfamily cell surface protein
folded gastrulation	*fog*	Secreted protein required during *Drosophila* gastrulation
forkhead	*fkh*	Transcription factor that promotes cell shape change
frazzled	*fra*	Ig Superfamily transmembrane receptor involved in axon guidance
gleeful (lmd, minc)	*glee*	Zinc finger containing member of Gli superfamily essential for mef2 expression
groovin (short stop)	*shot*	EF-hand gene family; expressed in muscle attachment sites
heartless (DFR1)	*htl*	Fibroblast growth factor receptor; required for morphogenesis of the mesoderm and tracheal system
hedgehog	*hh*	Secreted signaling factor
hibris	*hbs*	Ig Superfamily transmembrane protein expressed in muscles
inflated	*if*	α_{PS2} integrin subunit associated with cell:cell and cell:matrix adhesion; associated with muscle attachment
inscutable (nem)	*insc*	Cytoplasmic protein associated with asymmetric division (of founder cells)
irregular-optic chiasma C (roughest)	*rst*	Ig Superfamily transmembrane protein; substitutes for duf/kirre in myoblast fusion

Continued

Appendix Continued

Name	*Abbr.*	*Structure and/or apparent function of encoded gene*
jelly belly	*jeb*	LDL receptor repeat containing secreted protein associated with fusion of visceral myoblasts
kin of irre (*duf*)	*kirre*	Ig Superfamily transmembrane protein expressed in founder myoblasts; redundant function with IrreD/rst in fusion of these myoblasts
kruppel	*kr*	Homeodomain containing protein; muscle identity gene
ladybird	*lb*	Homeodomain containing protein;
lameduck (minc, glee)	*lmd*	Zinc finger containing member of Gli superfamily essential for mef2 expression
lethal of scute	*l(1)sc*	bHLH containing transcription factor; expressed in myoblast clusters
masquerade	*mas*	Protease associated with plasma membrane
meso18E		Novel mef2 regulated nuclear protein
msp-300		Spectrin-related molecule expressed in sarcomere and muscle attachment sites
M-spondin	*mspo*	Extracellular matrix protein
muscle segment homeobox	*msh*	Homeodomain containing transcription factor
muscleblind	*mbl*	Nuclear Cys-His zinc finger containing protein associated with muscle attachment
myoblast city	*mbc*	SH3 and DH domain containing cytoplasmic protein essential for myoblast fusion
myoblasts-incompetent (lmd, glee)	*minc*	Zinc finger containing member of Gli superfamily essential for myoblast specification
myocyte enhancer factor 2	*mef2*	MADS box containing transcription factor essential for myoblast morphogenesis
myosin heavy chain	*mhc*	Component of muscle sarcomere
myospheroid	*mys*	B_{PS} integrin subunit associated with muscle attachment
nautilus	*nau*	bHLH containing MRF family member; muscle identity gene
neuromusculin	*nrm*	Ig Superfamily transmembrane protein associated with larval muscles
not-enough-muscles (insc)	*nem*	Cytoplasmic protein associated with asymmetric division (of founder cells)
numb		Cytoplasmic/plasma membrane associated protein asymmetrically distributed in muscle progenitors
Paramyosin	*Prm*	Muscle structural protein
PAR-domain protein 1	*Pdp1*	PAR-domain bZIP transcription factor that regulates Mef2
Pox-meso	*Poxm*	Paired-domain containing protein expressed in the somatic mesoderm
rolling pebbles (ants)	*rols*	Ring Finger, Ankyrin repeat, TPR, coiled coil containing cytoplasmic protein essential for myoblast fusion
rolling stone	*rost*	Novel protein associated with myoblast fusion
roughest(irreC)	*rst*	Ig Superfamily transmembrane protein; substitutes for duf/kirre in myoblast fusion
S59/slouch	*slou*	Homeodomain-containing protein; muscle identity gene
sallimus (D-titin)	*sls*	Filamentous protein that is a component of muscle sarcomeres
sanpodo	*spdo*	Tropomodulin-like protein associated with asymmetric division of muscle progenitors
serpent	*srp*	GATA-like zinc-finger transcription factor expressed in midgut primordia
short stop(Groovin)	*shot*	Actin binding protein involved in axon guidance
shotgun	*shg*	DE-cadherin cell adhesion molecule
sidestep	*side*	Ig Superfamily transmembrane protein involved in targeting axons to muscle
singles-bar		Involved in myoblast fusion
snail	*sna*	Zinc-finger containing transcription factor essential for mesoderm formation
sticks-and-stones	*sns*	Ig Superfamily transmembrane receptor expressed in fusion competent cells and essential for myoblast fusion
stripe	*sr*	Zinc-finger containing nuclear protein involved in muscle attachment
tinman	*tin*	Homeodomain containing protein involved in heart development
Toll	*Tl*	Cell surface glycoprotein
Tropomyosin 1	*Tm1*	Component of sarcomere
upheld	*up*	Troponin T; component of sarcomere
twist	*twi*	bHLH-containing transcription factor essential for mesoderm specification; promotes myogenic differentiation
vestigial	*vg*	Novel nuclear protein; muscle identity gene
wingless	*wg*	Wnt-family member
zfh1		Zinc finger homeodomain protein expressed in pericardial cells and fat body; perturbations in muscle development
vimar		15 tandem armadillo repeats; expressed in visceral musculature

2.2 The Development of the Flight and Leg Muscle

J O Vigoreaux, University of Vermont, Burlington, VT, USA
D M Swank, San Diego State University, San Diego, CA, USA

2.2.1. Introduction

2.2.1.1. Scope of the Review

This review will examine the cellular and molecular events that transpire during the development of the adult leg, jump, and flight muscles of insects. All adult muscles are striated and, like their counterparts in vertebrates (skeletal muscle), consist of three principal cellular components: mitochondria, myofibrils, and membrane systems (sarcoplasmic reticulum (SR) and T tubules). The functional properties of each muscle arise from the interplay among these three components (Lindstedt *et al.*, 1998; Rome and Lindstedt, 1998). There is very little understanding of the developmental and regulatory mechanisms that establish the relative proportions of these functional units in the muscle cell (see Section 2.2.3.3.3). In contrast, major advances have been made in identifying early events in cell determination and the process by which structural proteins assemble into ordered myofibrils. These topics will be the subject of this review. Given the preeminent position of the fruit fly *Drosophila melanogaster* as a model organism in biological research, this species will serve as the focal point of this review. For comparison, the important contributions from other insect groups are also discussed. For additional information regarding myogenesis and muscle development, the reader is referred to **Chapter 2.1** in this encyclopedia.

2.2.1.2. Muscle Type Definitions

Insect flight muscles are classified functionally as direct (DFM) or indirect (IFM), physiologically as asynchronous or synchronous, and morphologically as tubular, close-packed, or fibrillar. The leg and jump muscles are invariably tubular and synchronous. The following are brief definitions of these and other terms that will be used throughout this chapter (for additional details see: Tregear, 1977; Crossley, 1978; Squire, 1986; Bernstein *et al.*, 1993; Dudley, 2000; Josephson *et al.*, 2000).

- Indirect flight muscles (IFM): Power-producing muscles that move the wings indirectly by deformation of the thoracic exoskeleton (Crossley, 1978). The IFM consist of two perpendiculary oriented, antagonistic muscles: the dorsolongitudinal muscles (DLM) and dorsoventral muscles (DVM) (**Figure 1a**). The DLM extend nearly

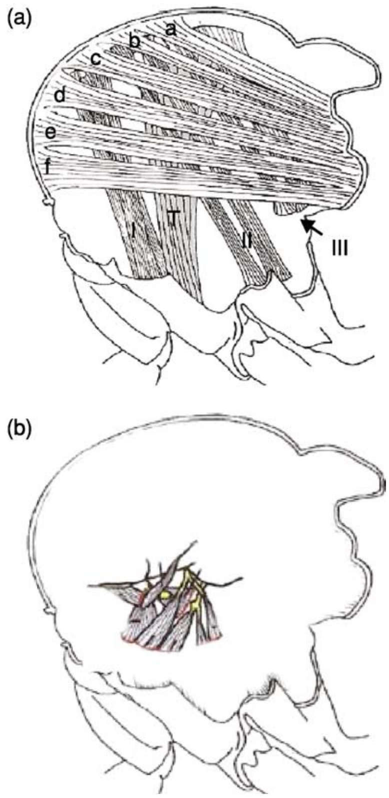

Figure 1 Major thoracic muscles in *Drosophila*. (a) Schematic diagram of a midsagittal section showing the right hemithorax of an adult fly. The six dorsolongitudinal muscle (DLM) fibers are labeled a–f and the three dorsoventral muscles (DVM) are labeled in roman numerals. DVM I consists of three fibers, and DVM II and III of two fibers each. The jump muscle (TDT) is labeled T. Anterior is to the left and dorsal at the top. (b) As (a) but with indirect flight muscles (IFM) removed to view the flight control muscles (DFM). (Modified from Rivlin, P.K., Schneiderman, A.M., Booker, R., **2000**. Imaginal pioneers prefigure the formation of adult thoracic muscles in *Drosophila melanogaster*. *Devel. Biol.* *222*, 450–459.)

parallel to the long body axis while the DVM extend from the tergum to the sternum. DLM function as wing depressors (downstroke) and their contraction stretches the DVM, which in turn contract to elevate the wings (upstroke) and stretch the DLM.

- Direct flight muscles (DFM): Muscles that act directly on the wing base. The power-producing muscles of primitive insects (e.g., Odonata) are directly attached to the base of the wings and their contractions bring about "direct" flapping of the wings. These muscles are also involved in rotation of the wings. In some insects (e.g., Orthoptera), the mesothoracic DVM are also used in walking. In insects with IFM (e.g., Diptera, Hymenoptera, and Coleoptera), the "power" DVM (asynchronous and fibrillar) and the "steering" DFM (synchronous and tubular) are distinct muscle groups; the latter group produces low power and functions only as control muscles (**Figures 1b** and **5**).
- Fibrillar: Large diameter fibers from which well-defined, large diameter and circular myofibrils can be easily dissociated. Found only in the flight muscles of Coleoptera, Hymenoptera, Diptera, Strepsiptera, Hemiptera, and Thysanoptera, and some Homoptera and Psocoptera (Cullen, 1974; Dudley, 2000). The term fibrillar is synonymous with asynchronous and myogenic (Pringle, 1977; Josephson *et al*., 2000).
- Tubular: Nuclei are located in a central position surrounded by columns of rectangular myofibrils. These muscles typically have a high proportion of sarcoplasmic reticulum (~20% of total volume) and low mitochondrial content (~5% volume). They are found commonly in leg muscles but also in some flight muscles (e.g., Odonata). The highly specialized jump muscle (tergal depressor of trochanter or TDT) is a mixed fiber-type tubular muscle that differs histochemically from other tubular muscles and from the IFM (Deak, 1977a; O'Donnell *et al*., 1989). It is the largest of all the tubular muscles in the adult and its primary function is to initiate flight (**Figure 1a**).
- Close packed: Characterized by small myofibrils evenly interspaced with mitochondria. These muscles are found in higher Orthoptera, Trichoptera, and Lepidoptera.
- Asynchronous: Oscillatory muscles in which the frequency of contraction is decoupled from the frequency of activating neuronal impulses. Asynchronous muscles thus attain much higher contraction rates than synchronous muscles and produce higher wing beat frequencies. This type of muscle is common among small insects (flies and bees) and some bugs (see fibrillar).
- Synchronous: Muscles in which the frequency of nervous stimulation and contraction are congruent. Synchronous flight muscles are nonfibrillar and phylogenetically ancestral to asynchronous muscles. They are found in insects with primitive flight muscles and larger wings such as locusts, moths, and butterflies.

2.2.2. Fate Specification and Cell Determination

2.2.2.1. General Features Established by the Early Studies

The general principles established by the early studies on this topic were previously reviewed in depth (Nuesch, 1985; see also **Chapter 2.1**). The developmental mechanisms of insect flight and leg muscle

can be broadly classified depending on whether the insect goes through a pupal transition to reach adulthood (holometabolous), or lacks a pupal transition (hemimetabolous) (Teutsch-Felber, 1970). In hemimetabolous insects, such as the cockroach *Periplaneta americana*, the complete set of adult muscles is already present in the larval form and most muscles (except flight and genital) are in full use. Larval muscles do not degenerate; instead, they are all taken over into the adult form. The flight muscles do not undergo much of a transition. Flight muscles are often present at hatching, remain small until the last larval stage, and reach their full size only before or even after the last molt. The little change that does occur takes place in the last larval stage, and involves growth by fiber splitting and an increase in the number of myofibrils. The leg muscles grow in pace with the rest of the body.

This scenario is in sharp contrast to adult muscle development during pupation of holometabolous insect (Nuesch, 1985; **Chapter 2.1**). In these insects, most of the larval muscles degenerate and new muscles develop, depending on the morphology of the adult. Larval muscles may or may not contribute to the adult muscle set; the muscles that do not contribute are removed by phagocytes (Hufnagel, 1918; Nuesch and Bienz-Isler, 1972; **Chapters 2.1** and **2.3**). Contributing larval muscles have been called "transformation muscles" but are now referred to as "larval templates," "persistent larval fibers," or "larval precursors." A typical example where larval tonic muscles are replaced by the adult phasic DLM is *Antheraea* and other Lepidoptera (Hufnagel, 1918; Nuesch, 1985; **Chapter 2.1**). During the prepupal stage the larval fibers structurally degenerate. In the pupal stage the degenerated larval fibers associate with multiplying mononucleated myoblasts to form the adult muscle anlage. Adult muscle development is initiated by fusion of myoblasts with the degenerated larval fibers. Fusion and cell membrane breakdown of larval fibers appears to be initiated by contact with the myoblasts (Stocker, 1974). The larval fibers separate from one another, grow, and elongate by fusing with more myoblasts, and finally divide into the individual adult fibers. In this insect, contractile proteins such as myosin and actin appear on day 8 of adult development (Bienz-Isler, 1968).

Similar mechanisms have been described for the IFM of the blowflies *Calliphora* and *Lucilia* (Peristianis and Gregory, 1971; Crossley, 1972). However, the primitive dipteran *Simulium*, and the wax moth, *Galleria mellonella*, use a *de novo* formation mechanism, at least for the DVM, that does not involve larval muscle. Instead, myoblasts proliferate during metamorphosis and fuse to form the adult flight muscles (Hinton, 1959, Sahota and Beckel, 1967).

Leg muscles generally also use a *de novo* mechanism. Muscle pioneers (MPs) in the grasshopper leg muscle were the first identified as organizing cells in myogenesis (Ho *et al.*, 1983, Ball and Goodman, 1985). An MP cell serves as a focus for smaller migrating mesodermal cells that collect nearby and fuse with it. The large MP then cleaves into parallel muscle fibers. Thus, a single MP delineates a single bundle of muscle fibers.

Motor nerves have also been well investigated in terms of their role in adult muscle formation (Nuesch, 1985; **Chapters 2.3** and **2.5**). The role of the nervous system in controlling flight muscle development and maintenance was examined by surgically severing neural connections feeding the muscles (e.g., removal of thoracic ganglia), just before or during larval/pupal development (Nuesch, 1968). Studies in *Antheraea* showed that denervation early in development resulted in a more pronounced muscle defect than denervation late in development. Denervation, however, delayed development but did not prevent it (Basler, 1969). In saturniid moths, denervation affected the anlagen, whereas in hemimetabolous insects (crickets, cockroaches) it affected only the differentiated, active muscles. The main affect of denervation appeared to be on nuclear division (Eigenmann, 1965). Despite the presence of clear differences among species on how nerve may exert its effects, all early studies suggested that nerves have an important function in the development and maintenance of muscles. Furthermore, although the mechanisms by which nerves influence muscle developmental decisions remained undefined, several studies pointed to a possible role in the provision of trophic factors (Nuesch, 1985; **Chapter 2.5**).

The motor nerves themselves are remodeled during the pupal transition (see **Chapters 2.3–2.5**). In the saturniid *Antheraea* and other Lepidoptera, larval motor nerves degenerate at their contact points with the larval muscles, from which new nerve sprouts will grow into the adult anlagen. During this time, the motor nerves undergo transformation from larval slow to adult fast nerve cells (Nuesch, 1955, 1985; Heinertz, 1976).

Hormones play a prominent role in adult muscle development. Thus, 20-hydroxyecdysone (20E; the molting hormone), for example, triggers profound metamorphic changes by inducing larval muscles to break down, stimulating imaginal discs to grow and differentiate, and reprogramming certain larval muscles to become adult muscles (Truman, 1973; **Chapters 2.4** and **2.5**). In contrast, juvenile hormone (JH) is responsible for the maintenance of existing

structures (Wilde and DeBoer, 1961). This was demonstrated in *Rhodnius prolixus*, where injection of JH temporarily prevents the breakdown of larval muscles during pupation (Lockshin and Williams, 1964).

The developing epidermis was also shown to influence muscle development, primarily the orientation of the muscle fibers. Thus, moving pieces of the epidermis of *Galleria mellonella* by 180° relative to the muscle development site, caused the DLM to reorient in order to maintain the same epidermis attachment sites (Sahota and Beckel, 1967). Furthermore, in some *Drosophila* homeotic mutants lacking wings, the duplication of cuticle structures was accompanied by considerable rearrangement of the thoracic muscles, but the muscles themselves were not duplicated (Deak, 1978).

In summary, by 1985, nerves, hormones, and epidermal influences had been implicated in muscle development, but their precise role remained largely undefined. Moreover, studies on genetic regulation were sparse. Research that has addressed some of these deficiencies are discussed in the following sections.

2.2.2.2. Precursor Cells

In holometabolous insects, adult muscle precursor cells are determined before metamorphosis. Precursors for both the flight and leg muscles arise from the mesoderm (see **Chapter 2.1**). Adult muscle precursors originate as sister cells of embryonic founders (reviews: Becker and Bernstein, 1994; Baylies *et al*., 1998; Frasch, 1999; Consoulas *et al*., 2000; see also **Chapter 2.1**) (**Figure 2**). Embryonic muscle founders and adult muscle precursors appear at well-defined locations during the final mitotic division of somatic mesodermal cells, and differ from the surrounding myoblasts by their specific expression of regulatory genes (often referred to as "muscle identity genes") such as *twist* (*twi*), a helix–loop–helix transcription factor (**Table 1**). In vertebrates, Twist functions by directly inhibiting the ability of myogenic regulators like myocyte enhancer factor-2 (Mef-2) to bind to their target genes to activate transcription. Expression of *twist* in *Drosophila* ectoderm drives the cells into myogenesis (Baylies and Bate, 1996) (see also **Chapter 2.1**).

Larval mesoderm cells that will become embryonic and larval muscles gradually lose expression of *twist*, fuse and differentiate into various embryonic muscle types. Myoblasts that will become adult muscle cells persist in *twist* expression, postpone differentiation and proliferate actively during the larval stage (Bate *et al*., 1991; Fernandes *et al*., 1991) (**Figure 2**). Broadie and Bate (1993) demonstrated, by hydroxyurea ablation of *twist*-expressing cells in the late embryo, that larval mesodermal lineages expressing high

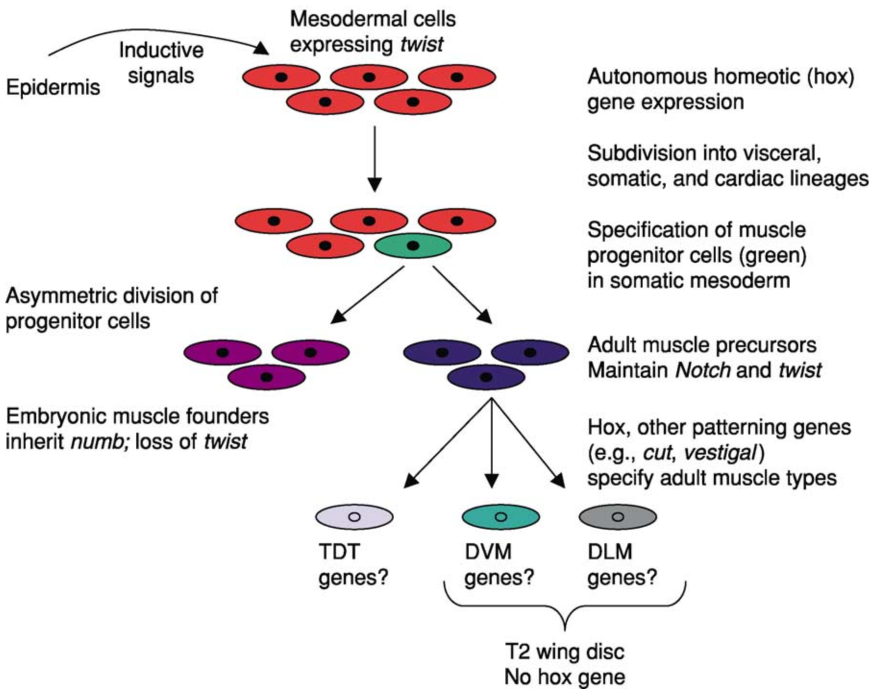

Figure 2 Specification of adult muscle precursors during embryogenesis of *D. melanogaster*. Major morphological divisions, autonomous gene expression, and inductive cues are shown. Genes known to be expressed in myoblasts that contribute to each of the three major muscle groups in the adult thorax are also listed.

Table 1 Genes involved in flight and leg muscle development

Gene[a]	*Description*	*Primary function(s)*	*Reference*
twist (*twi*)	Helix–loop–helix transcription factor	Expression prevents differentiation of adult mesoderm during embryogenesis; regulates *D-mef2* expression.	Baylies and Bate (1996), Cripps and Olson (1998)
Notch (*N*)	Transmembrane receptor	Maintains undifferentiated state, likely through regulation of *twist* expression	Anant *et al.* (1998)
numb (*nb*)	Membrane-associated protein	Blocks N-mediated repression of differentiation	Ruiz Gomez and Bate (1997)
erect wing (*ewg*)	Transcription factor	Required for IFM formation, perhaps involved in fusion of myoblasts to IFM	DeSimone *et al.* (1996), Roy and VijayRaghavan (1999)
Drosophila myocyte enhancer factor 2 (*D-mef2*)	MADS domain transcription factor	Activates transcription of muscle genes during differentiation	Ranganayakulu *et al.* (1995)
cut	Transcription factor	Expressed in myoblast that will become DFM	Sudarsan *et al.* (2001)
vestigal (*va*)	Transcription factor	Expressed in myoblast that will become IFM	Sudarsan *et al.* (2001)
scalloped (*sd*)	Transcription factor	Expressed in adult myoblasts	Roy and VijayRaghavan (1999)
heartless (*htl*)	Fibroblast growth factor receptor	Expressed in adult myoblasts	Roy and VijayRaghavan (1999)
Antennapedia (*Antp*)	Homeodomain transcription factor	Expressed in haltere imaginal discs	Roy and VijayRaghavan (1999), Roy *et al.* (1997)
Sex combs reduced (*Scr*)	Homeodomain transcription factor	Expressed in myoblasts associated with ventral leg imaginal discs	Roy and VijayRaghavan (1999), Roy *et al.* (1997)
Ultrabithorax (*Ubx*)	Homeodomain transcription factor	Expressed in abdominal muscles and T3 epidermis	Roy and VijayRaghavan (1999), Rivlin *et al.* (2001)
Octopod (*Octo*)	Homeodomain transcription factor (*Manduca*)	Mutation causes additional set of legs with poorly developed homeotic muscles	Miles and Booker (1993)
dumbfounded (*duf*)	Immunoglobin superfamily	Required for DFM myoblast aggregation and fusion	Ruiz Gomez *et al.* (2000)
apterous (*ap*)	Homeodomain transcription factor	Expressed in DFM founder cells	Kozopas and Nusse (2002)

[a]Genes listed in order of appearance in this chapter.
MADS, MCM1-Agamous-Deficiens-SRF; DFM, direct flight muscles; IFM, indirect flight muscles.

levels of *twist* give rise to specific subsets of muscle fibers within the adult legs. Each primordium showed a unique fate and, after ablation, could not be replaced by neighboring cells. The authors concluded that fate restriction of myoblast pools in early development defined the elements of the final adult muscle pattern. This could be due to genetic determination within the mesoderm, and/or to spatial isolation of otherwise equivalent cells.

Persistent *twist* expression in the mesoderm appears to require *Notch* (*N*) gene expression. *Notch* expression is maintained in mesodermal sister cells that do not express the *numb* (*nb*) gene after asymmetric division of parent mesoderm cells (Ruiz Gomez and Bate, 1997; Anant *et al.*, 1998; review: Roy and VijayRaghavan, 1999) (**Figure 2**). Twist is a regulator of various transcription factors. For example, *erect wing* (*ewg*), which encodes a DNA binding protein, is expressed in myoblasts at the earliest stages of IFM differentiation, 10 h after puparium formation (APF) as *twist* expression declines (DeSimone and White, 1993; DeSimone *et al.*, 1996). This correlation suggests a negative regulation of *ewg* by Twist. The *Drosophila* homolog of the vertebrate *myocyte-specific enhancer factor 2* (*D-mef2*), a MADS domain transcription factor that acts as a transactivator of muscle specific differentiation genes, is likely also to be regulated by Twist (MADS is an acronym formed from the initials of the first four discovered members of this gene family: MCM1, Agamous, Deficiens, and SRF). The focal point of *D-mef2* function is myoblast differentiation; this protein is expressed in adepithelial cells (precursors of adult muscle) that are attached to the wing, haltere, and leg imaginal discs in the third larval stage (review: Roy and VijayRaghavan, 1999).

In the third instar larva, the expression of genes encoding other transcription factors, i.e., *cut, vestigial* (*vg*), *scalloped* (*sd*), and *heartless* (*htl*), is correlated with *twist* expression in myoblasts (Roy and VijayRaghavan, 1999). Sudarsan *et al.* (2001) investigated the contribution of two of these genes, *cut* and *vestigial*, to the diversification of myoblasts in third instar wing discs. Vestigial and low levels of Cut are expressed in myoblasts that will contribute to IFM. In contrast, high levels of Cut but not Vestigial is required in myoblasts for formation of DFM. Vestigial and Cut expression is stabilized by a mutually repressive feedback loop (Sudarsan *et al.*, 2001).

By the pupal stage of *Drosophila*, adult thoracic muscle precursors have proliferated to produce a pool of *twist*-expressing imaginal myoblasts that are associated with wing and leg imaginal discs in the thoracic segments (Bate *et al.*, 1991; Fernandes *et al.*, 1991) (**Figure 3**). Smaller, separate pools of myoblasts are associated with peripheral nerves in the thorax and presumably contribute to the generation of the muscles that the specific nerves will innervate. Myoblasts on the wing disc are not genetically restricted to become flight muscle, however. When myoblasts from third instar larval wing discs are transplanted into mature host larvae, they contribute to muscles in both the abdomen and thorax of the adult host (Roy and VijayRaghavan, 1999). Thus, the earlier presumption that all myoblasts from *Drosophila* wing discs give rise to flight muscle and all myoblasts from the leg disc give rise to leg muscles (Roy and VijayRaghavan, 1999), appears to be an overgeneralization. This is discussed further below (see Section 2.2.2.5.2).

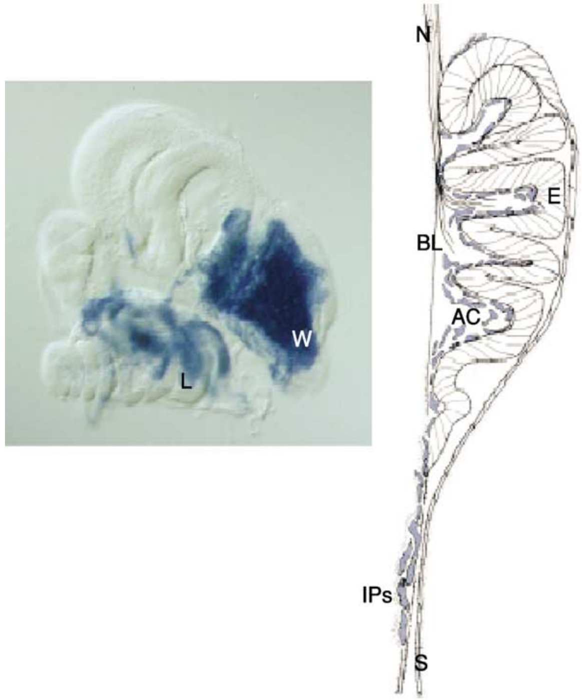

Figure 3 Myoblasts and muscle pioneers in *Drosophila* imaginal discs. The light micrograph on the left shows a wing disc (W) and a leg disc (L). The areas stained in blue contain *twist*-expressing cells as evidenced by the expression of a *twist*-lacZ transgene. The drawing on the right is a sagittal view of a second thoracic (T2) leg disc. The adepithelial cells (AC, light blue) are the imaginal myoblasts that reside in the cavity formed by the disc epithelium (E) and the basal lamina (BL). A morphologically distinct class of imaginal myoblasts is found associated with the stalk (S) that attaches the disc to the epidermis. This group of cells represents the imaginal pioneers (IPs). N, nerve. (Reprinted with permission from Rivlin, P.K., Schneiderman, A.M., Booker, R., **2000**. Imaginal pioneers prefigure the formation of adult thoracic muscles in *Drosophila melanogaster*. *Devel. Biol. 222*, 450–459; © Elsevier.)

2.2.2.3. Patterning

How are the *twist*-expressing cells partitioned into the proper segments so that some will give rise to flight muscle and some to jump muscle? This occurs primarily through the action of epidermal signals and Hox genes.

2.2.2.3.1. Role of the epidermis The epidermis plays an important role in myoblast migration to muscle development sites. VijayRaghavan *et al.* (1996) followed the paths of imaginal myoblast migration from wing and leg discs. Wing or leg discs were transplanted onto the thorax or abdomen of pupal hosts. In these animals, the myoblasts from both discs migrated over the host epidermis when transplanted onto pupal thorax, but no migration occurred when the transplantation site was on the abdomen. The resulting flies had ectopic wings or legs. The migration path cues from the epidermis may be due to expression of Hox genes (Roy and VijayRaghavan, 1997). Epidermal cells also contribute to the formation of muscle attachment sites (see Section 2.2.3.3.2).

2.2.2.3.2. Role of Hox genes Homeotic selector (Hox) genes are widely known from their mutations in *Drosophila*, which result in gross duplications or transformations of body segments (see **Chapter 1.8**). A dramatic example is the "four winged" fly, which results from the absence of expression of *Ultrabithorax* (*Ubx*) in the third thoracic segment (T3), where the haltere and leg discs reside (Fernandes *et al.*, 1994). Hox genes influence, directly or indirectly, the segment-specific diversification of the mesoderm into exact muscle patterns (review: Roy and VijayRaghavan, 1999). For example, expression of *Antennapedia* (*Antp*) in mesoderm is specific to

myoblasts that are associated with the haltere disc in the T3 segment. In contrast, myoblasts on the wing disc in the second thoracic segment (T2) do not express any Hox genes (Roy *et al.*, 1997). Thus, any influences of Hox genes must occur indirectly through inductive cues from the ectoderm (Rivlin *et al.*, 2001).

Initial studies of Hox gene expression in the "four winged" fly of *Bithorax-Complex* (*BX-C*) mutants suggested that *Ubx* expression has little or no influence on adult thoracic muscle patterning (Fernandes *et al.*, 1994; Roy *et al.*, 1997). Even though T3 is transformed in such a way that the epidermis looks like the second segment, the haltere disc myoblasts associated with the transformed segment continue to express *Antp* and do not transform into IFM-like muscles (Roy and VijayRaghavan, 1999). However, a recent investigation of *Ubx* regulatory mutations (*anterobithorax, bithorax, postbithorax*, and *bithoraxoid*) acting on the adult T3 musculature suggests an indirect role for *Ubx* in thoracic muscle patterning (Rivlin *et al.*, 2001). Almost all mutant allele combinations tested by Rivlin *et al.* (2001) resulted in homeotic IFM and DFM in the transformed T3 segment. While the amount and/or quality of homeotic IFM increased in the transformed segment, the amount of homeotic DFM did not vary significantly as the severity of the ectodermal transformation increased. Because *Ubx* is not expressed in adult T3 mesoderm, the results suggest that inductive cues play a major role in the patterning of adult thoracic muscles.

Hox genes also play a role in muscle patterning along the dorsal–ventral axis within a segment. *Sex combs reduced* (*Scr*) is exclusively expressed in myoblasts associated with ventral leg imaginal discs in all thoracic segments (Glicksman and Brower, 1988a). Misexpression of *Scr* in wing disc-associated precursors of dorsal muscles (IFM and DFM) disrupts the development of these muscles (Glicksman and Brower, 1988b; Roy and VijayRaghavan, 1999).

Myoblasts expressing a specific homeotic selector gene can fuse with myoblats expressing a different homeotic selector gene (i.e., different segmental identities). For example, myoblasts transplanted from the thorax to the abdomen readily fuse with resident myoblasts and are incorporated into abdominal muscles (Roy and VijayRaghavan, 1997). However, once fused, myoblasts from Hox mutants often cannot carry out their original differentiation program. Thus, misexpression of *Ubx* in the developing IFM causes suppression of a thoracic specific actin gene, *Act88F.* Conversely, loss of function of *Ubx* in abdominal muscles results in the ectopic transcription of *Act88F* (Roy and VijayRaghavan, 1999).

Hox genes are likely to be conserved in all insects. *Ubx/abdominal-A* genes have been studied in the grasshopper embryos (Kelsh *et al.*, 1994), and the homeotic mutation *Octopod* (*Octo*) has been studied in *Manduca* (Miles and Booker, 1993). *Octopod* transformed the ventral epidermis of the first abdominal segment into a T3. This resulted in the presence of thoracic-type legs attached to the abdominal segment with the legs containing homeotic leg muscles.

2.2.2.4. Degeneration of Larval Muscles

During metamorphosis of holometabolous insects, most embryonic muscles degenerate and are replaced by adult specific muscles (see **Chapter 2.5**). In *Drosophila*, histolysis of the embryonic muscles begins with the elimination of most muscles in the head and thoracic segments soon after the onset of the white prepupal stage (Fernandes *et al.*, 1991). The signal for this programmed cell death comes from the anterior region, presumably the head. The timing of the signal suggests that the eclosion hormone may be involved in this process (Kimura and Truman, 1990).

Rheuben (1992) described the ultrastructural changes in the larval mesothoracic muscle associated with the early stages of degeneration in *Manduca*. The muscle fibers decreased in cross-sectional area but increased in apparent surface area. Large numbers of electron-dense granules or droplets are formed and extruded from the muscle cytoplasm. The thick basal lamina is specifically removed, and this may be essential for subsequent fusion of myoblasts to the residual larval myofibrils. Contractile elements degenerate, tracheoles withdraw, and mitochondria appear to degenerate (Rheuben, 1992; Sonea and Rheuben, 1992).

However, not all larval muscles degenerate in holometabolous insects. Some adult muscles differentiate using remnants of the larval fibers as templates. An example of this is the DLM discussed below (see Section 2.2.2.5).

2.2.2.5. Formation of the Indirect Flight Muscles

In dipterans, the IFM are composed of two opposing sets of muscle fibers, the DLM and DVM that attach directly to the thoracic cuticle (**Figure 1**). These muscles have generally been assumed to have identical physiological characteristics and the same protein isoform profile (Lebart-Pedebas, 1990). This, however, has not been rigorously tested and prominent exceptions have been reported. In *Drosophila*, these muscles have different origins and are regulated by different developmental mechanisms.

2.2.2.5.1. The dorsolongitudinal flight muscle (DLM) The DLM formation in the *Drosophila* musculature occurs by transformation of pre-existing larval muscles into adult fibers. Larval scaffolds are employed for its generation instead of founder cells (used in embryonic muscle patterning) (see **Chapter 2.1**). Three mesothoracic muscles of the second thoracic segment of the larval body wall survive histolysis and undergo radical transformations (Fernandes *et al*., 1991). The persistent larval fibers "dedifferentiate" 10 h APF. Starting at 6 h APF, a series of vacuoles appear and the larval fibers show a decrease in birefringence. At 10 h APF, the fibers are highly vacuoled and distorted in shape. By 12 h APF, myofibril organization has degenerated and fibers have started to elongate (**Table 2**).

The primary source of myoblasts for fusion to the larval scaffolds is the imaginal wing disc (**Figure 3**). The myoblasts are located between the folds of the wing imaginal disc, and are termed adepithelial cells (ACs) (Bate *et al*., 1991). In contrast, myoblasts that will become leg and TDT muscles, as well as some that will contribute to the DVM, arise from mesothoracic leg discs (Bate *et al*., 1991).

Just after pupation, the wing discs evert and release myoblasts. The myoblasts migrate to the larval templates, possibly using the flight muscle motor nerves as guides (Fernandes *et al*., 1991) (**Figure 4**). However, these are not necessarily the first myoblasts to arrive on site; myoblasts associated with peripheral larval thoracic motor nerves may be another source of DLM components. By 14 h APF, *twist*-expressing myoblasts have surrounded the persistent larval muscles. At 14–18 h APF, the three larval fibers split longitudinally thus generating six fibers per half thorax (**Table 2**). Myoblasts fuse and the templates grow in size. Fernandes *et al*. (1991) suggested that larval templates have a similar function as the muscle pioneers in grasshopper embryos (Ho *et al*., 1983), i.e., persistent larval muscles partition the initial pool of myoblasts among themselves.

To test this and other possible roles of the persistent larval muscle fibers (MFs), Farrell *et al*. (1996) used lasers to ablate one, two, or all three larval fibers (MF9, MF10, and MF19). Surprisingly, in the absence of larval muscle fibers, the DLM still developed. Thus, the larval fibers are not required to initiate myoblast fusion, specify total DLM fiber volume, or locate the DLM in the thorax. However, the larval fibers are required to establish the correct number of adult fibers. For example, if only one fiber is ablated (e.g., MF9), development of the other two fibers proceeds normally, but the resulting IFM has a variable number of fibers (from four to six or more) (Farrell *et al*., 1996; Fernandes and Keshishian, 1996; Roy and VijayRaghavan, 1999). It has been postulated that the appropriate number of fibers is achieved by controlling the partitioning of myoblasts between the larval scaffolds.

Larval muscles are also not required for establishing DLM identity. *De novo* fibers that form after ablation express the correct actin gene (*Act88F*), and have normal innervations and normal insertion sites (Fernandes and Keshishian, 1996). Thus, larval scaffolds are not true muscle organizers in the same sense of muscle founders in embryogenesis.

By 20 h APF (**Table 2**), there are six clearly visible developing DLM template fibers (Fernandes *et al*., 1991). Three rows of nuclei are visible within each fiber. By 24 h APF, an additional row of nuclei has appeared. Fusion of myoblasts with the developing DLM is completed by 28 h APF. By 36 h APF, the developing IFM are approximately one-third of their final size (Fernandes *et al*., 1991).

Roy and VijayRaghavan (1998) showed that the splitting of the larval templates is concomitant with invasion by imaginal myoblasts and the onset of differentiation. In their study, blocking of myoblast proliferation by ectopic expression of a cell cycle inhibitor protein (the human cyclin dependent kinase inhibitor p21) prevented myoblast association with the persistent larval fibers. As a result, larval templates failed to split, suggesting that splitting is not an autonomous property of the persistent larval muscles. Instead, it requires interactions with myoblasts (Roy and VijayRaghavan, 1998). Nerves are not crucial for this, as laser ablation of the flight muscle motor nerve does not affect the development of the DLM (Fernandes and Keshishian, 1998) (see Section 2.2.2.9.1).

As mentioned earlier, *ewg* is expressed in myoblasts during their fusion to DLM larval scaffolds, and may act as an important genetic regulator in DLM splitting and differentiation. Loss of *ewg* function results in embryonic lethality. Viable alleles of *ewg* (hypoexpressors) cause severe abnormalities in IFM, including failure of founder DLM to split, and early degeneration of DLM and some DVM fibers. These observations suggest a crucial role for *ewg* in proper initiation of the IFM-specific differentiation program, most importantly influencing differentiation events downstream of fusion (DeSimone *et al*., 1996; Fernandes and Keshishian, 1996).

As indicated above (see Section 2.2.2.2), *ewg* may be regulated by *twist*. The influence of *twist* on IFM development has been examined through the use of temperature sensitive alleles (Anant *et al*., 1998; Cripps *et al*., 1998; Cripps and Olson, 1998). When mutant pupae are switched to nonpermissive

Table 2 Sequence of events during IFM development and myofibril assembly in *Drosophila*

Molecular events	*Time*[a]	*Muscle morphology*	*Myofibril assembly*
twist-expressing myoblast in wing/leg imaginal disc	0	Larval body wall muscle intact	
stripe-expressing epidermal cells in notal region of wing disc			
stripe-expressing cells form clusters in the thorax	8	Three larval muscles (9, 10, 19) that persist to give rise to DLM are surrounded by myoblasts	
		Muscles become highly vacuoled and distorted in shape	
twist-expressing myoblasts and PS-2α expressing myoblasts surround persistent larval muscles	12	Adult-specific nerve outgrowth over elongating larval muscle templates and future DVM site	No remnants of larval muscle myofibrils
Act88F gene expression begins in DLM and DVM	16	Larval templates split longitudinally as wing disc-associated myoblasts fuse into them	
Clusters of *stripe*-expressing cells increase in size		Higher-order nerve branches arise	
No PS integrin expression		DVM visible	
No tubulin expression		Tendon cells contact myotubes	
One IP nucleus per DVM fiber	20	Muscle splitting complete and adult neuromuscular pattern is formed	
Muscle ends and their connecting epidermal processes express integrin		Filopodial extensions from DLM make contact with EMA	
		Occasional phagocytes engulfing unfused myoblasts	
Clusters of *stripe*-expressing cells at ends connecting muscle to epidermis	24	Epidermal tendon cell processes connecting DVM to dorsal muscle attachment are evident	Abundant microtubules, few stress fiber-like structures
Mhc expression begins	30	Myoblast fusion nearly complete	
No *twist* expression	38	Modified terminal Z band formed at MTJ	Thick and thin filaments appear
			Formation of individual myofibrils (310 sarcomeres ~1.7 μm long, three or four thick filaments across) within microtubule envelopes
		Muscles approx. half final size	
	48		Uniform length increases of thick and thin filaments
			Thin filaments grow from pointed end in the presence of 43 kDa TMOD
			Addition of new myofilaments to periphery of myofibril
			Regular Z bands and M lines detected
Expression of accessory proteins (e.g., FLN, A225)	60

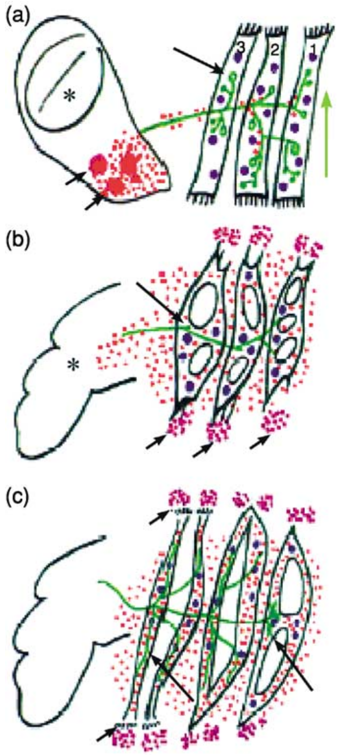

Figure 4 Early events in the development of *Drosophila* DLM. (a) Diagram showing a wing imaginal disc (asterisk) and three dorsal oblique muscles (numbered 1, 2, 3) in a late instar larva. Adepithelial cells (myoblasts) are shown in red and the larval muscle nuclei are shown in blue. Large red dots in the notal epithelium of the wing disc represent groups of *stripe*-expressing cells that will become the attachment sites for the DLM (purple dots in b and c). In addition to the disc, myoblasts are also seen associated with motor nerves (green) migrating towards the larval muscles. A synaptic bouton is indicated by the black arrow. The dorsal midline is indicated by the green arrow. (b) By 6–10 h APF, the disc has everted and the myoblasts are seen migrating over the heavily vacuolated remnants of the three larval muscles. The large arrow points towards a regressing motor neuron. (c) Longitudinal splitting of larval fibers is evident by 16 h APF. The templates will grow as myoblasts continue to fuse with them. New motor neuron connections are made over the splitting muscles (large arrows). (Reproduced with permission from Roy, S., VijayRaghavan, K., **1998**. temperatures, *twist* expression levels decrease causing a reduction in the number (from six pairs to only three) and volume of the DLM fibers. DFM, DVM, and jump muscles are not affected by these mutations even though contributing myoblasts to these muscles normally express *twist*. Cripps *et al.* (1998) showed that although *twist* is expressed in precursors of adult muscles throughout the larval and early pupal stages, *twist* is only required for DLM patterning during the late larval stage, just prior to the time the three larval scaffolds split to form the six templates. No splitting of DLM larval template fibers was observed in *twist* mutants. The authors speculate that this function of *twist* is mediated by *D-mef2*, since, in *D-mef2* hypomorphic mutants, splitting is also disrupted. In addition, hypomorphic mutations in *D-mef2* cause a reduction in DLM size and disrupt the patterning of DLM fibers (Lilly *et al.*, 1995; Ranganayakulu *et al.*, 1995). This observation supports the notion that *D-mef2* expression is dependent on *twist*.

Notch (N) also appears to be involved in the *twist* pathway, as a phenotype, similar to that described in *twist* mutants, is observed with N temperature sensitive alleles, i.e., reduced levels of N result in failure of DLM to divide (Anant *et al.*, 1998). A premature reduction in *twist* expression is observed when N is decreased. Evidence that N is a crucial signal for maintenance of *twist* expression comes from overexpression studies of N, which results in persistent *twist* gene expression, failure to complete differentiation (as evidenced by lower myosin and actin levels), and loss of DLM muscles in the adult (Anant *et al.*, 1998). No effect of N overexpression is observed in the DFM.

Similar to *Drosophila*, the hawk moth *Manduca sexta* uses pre-existing larval muscles as templates for DLM formation. The DLM arises from an anlage containing remnants of specific larval dorsal body wall muscles and extrinsic myoblasts. Using histology techniques, Duch *et al.* (2000) showed that larval template fibers degenerate and motor terminals retract from muscle fibers 2 days before pupation. Five larval fiber bundles are incorporated into the anlage, for adult DLM development, instead of being lost during the pupal transformation. Myoblasts accumulate and proliferate near the retracted motor nerve endings that persist around the degenerating larval template fibers. At 2 days APF, the anlage splits into five bundles, each innervated by one motor neuron. By day 7 APF, striations are observed and motor neurons reach the attachment sites. A key difference from *Drosophila* is that myoblasts do not originate from wing discs. Thus, ablation of the wing disc prevents formation of the wing but has no effect on DLM development. Instead, myoblasts arrive by several pathways to accumulate around the tufts of nerve terminals. A similar phenomenon is observed for myoblast accumulation in the *Manduca* leg muscle (see below). For this case, it has been suggested that a signaling molecule may be released from nerve terminal endings to attract the myoblasts (Duch *et al.*, 2000).

Cifuentes-Diaz (1989) studied DLM formation in *Pieris brassicae* (Lepidoptera) at the electron

microscopy (EM) and light microscopy level. As in *Manduca*, the DLM arise from two symmetrical pairs of dorsal mesothoracic larval muscles. Myoblasts migrate to the median region of these templates, along nerves and tracheae. Myoblasts proliferate and penetrate the larval fibers, and the fibers break into fragments. The developing anlage eventually re-forms into the five adult fibers. A major conclusion of the study was that myoblasts arise from exogenous sources, with few or none arising from degeneration of larval fibers.

The maturation of the adult IFM in the Colorado beetle, *Leptinotarsa decemlineata* is also different from that observed in *Drosophila*, specifically in terms of lack of imaginal characteristics (Smit and Velzing, 1986). In the prepupal period, the larval muscles (muscle *obliquus lateralis dorsalis*) dedifferentiate and fragment. The fragments contain very few myofibrils, and the sarcoplasmic reticulum and T-tubular system (see Section 2.2.1.1) is greatly reduced. Myoblasts develop from satellite cells, penetrate the muscle fiber, and fuse with the larval cell fragments. New myofibrils that have the characteristic adult filament lattice pattern appear after 2–5 days.

Novicki (1989) investigated the control of growth and ultrastructure of the cricket *Teleogryllus oceanicus* DLM flight muscle. The flight musculature in this hemimetabolous insect is initially patterned during embryogenesis. The analysis revealed that within 8 days from the start of the last nymphal instar, the DLM increased 15-fold in mass and acquired interfibrillar tracheoles, and the percentage volume occupied by mitochondria quadrupled. However, the myofibril and sarcoplasmic reticulum content decreased. An investigation into the neural and hormonal control of this process concluded that growth and remodeling are dependent on both innervation and JH, but maturation is more dependent on JH (Novicki, 1989).

Similarly, in the fifth larval instar of the hemimetabolous desert locust *Schistocerca gregaria*, the conversion of juvenile flight muscle into the high-energy-consuming adult form requires that mitochondria proliferate more rapidly than all the other cellular components, and requires the development of tracheoles (Wang *et al.*, 1993) (see Section 2.2.3.3.3).

An unusual case of DLM "development" is the flightless grasshopper, *Barytettix psolus* (Arbas and Tolbert, 1986). In this species, DLM are present and innervated during nymphal life, but these muscles are absent in adults. Despite the absence of muscles, however, the motor nerve persists in the adults.

2.2.2.5.2. The dorsoventral flight muscle (DVM) In contrast to DLM formation, DVM in *Drosophila* are formed by *de novo* fusion of imaginal myoblasts. At least some of these myoblasts arise from a pool separate from the one supplying myoblasts for the DLM. Rivlin *et al.* (2000) have provided the most recent analysis of how DLM arise in *Drosophila* by tracking the progression of *twist*-expressing cells from different imaginal disc pools. Prior to the third instar larval stage, a pool of *twist*-expressing myoblasts exists in the wing and the leg imaginal discs. All myoblasts and their nuclei are uniform in size. By the start of the third instar stage, *twist*-expressing cells containing nuclei that are twice the size (9–10 μm) of other cells are found in the stalk region of the T2 leg disc (**Figure 3**). There are up to five of these larger size cells that contain larger nuclei. These cells have been termed "imaginal pioneers" (IPs), as they appear to play a very similar role to muscle pioneers in embryogenesis, and share several morphological similarities, including the presence of microtubules (Rivlin *et al.*, 2000). In contrast, other *twist*-expressing cells have no microtubules. Upon leg disc eversion, the IPs take up the position of the adult fibers. They elongate to >75 μm by extending growth cones ventrally that anchor to the epidermis. Each DVM fiber is prefigured by a single IP. At 24 h APF, each DVM fiber appears as a syncytium of nuclei surrounded by individual myoblasts.

Earlier papers had reported that all myoblasts for the *Drosophila* DVM originate from the wing discs (e.g., Lawrence, 1982). Rivlin *et al.* (2000) stated that both discs provide myoblasts for the DVM, but only the leg disc provides DVM IPs. Fernandes *et al.* (1991) reported that myoblasts from leg discs take two paths, one group forming the leg muscles and the other group migrating dorsally to contribute to muscles in the ventral thorax. Perhaps a better general statement is that, in the thorax, the dorsal muscles arise from wing disc myoblasts and the ventral ones from the leg disc myoblasts. Since DVM are vertically aligned, myoblasts are contributed from both discs.

Lebart-Pedebas (1990) investigated similar DVM developmental questions in the primitive dipteran *Chironomus*. In contrast to *Drosophila*, the *Chiroyomus* DVM develop during the last larval instar, prior to metamorphosis. They are organized into two groups, one consisting of 10 fibrillar DVM and a second group of four that is split into two groups on either side of the TDT. The group of 10 develops from myoblasts fusing with larval muscle. The larval muscles dedifferentiate (lose myofibrils), but the large nuclei of the larval muscle are maintained in columnar-shaped fibers with which the

myoblasts fuse. The larval muscle has an unusual hollow shape with nerves innervating its inner surface. The muscle is connected to the imaginal leg disc, so that the hollow cavity communicates with the ACs present in the disc. However, no migration of myoblasts is observed from the imaginal disc toward the larval muscle or vice versa, suggesting that the DVM develop from an anlage that is independent of the imaginal disc. The author proposed that myoblasts migrate with hemolymph to arrive at the anlage. Thus, in this species, both the DVM and DLM are formed using larval templates.

How does the artificial *de novo* fusion of DLM myoblasts resulting from laser ablation of larval templates compare to cases where DVM development does not rely on larval templates? Fernandes and Keshishian (1996) found that, at 14 h APF, myoblasts that would have fused with the ablated larval scaffold, instead clustered (four to six cells) in the region of the ablated fiber and lined up end-to-end, similar to the way in which DVM myoblasts line up. The subsequent fusion process was very similar to DVM fusion. Is one mode of flight muscle formation evolutionarily ancestral to the other? Rivlin *et al.* (2000) made the point that *Drosophila* DVM can have a variable number of fibers. This is not seen in DLM unless the larval scaffolds are ablated. Thus, perhaps the scaffold mechanism has evolved as a way of ensuring proper fiber number. Whether this is, in fact, the case, has yet to be demonstrated.

2.2.2.6. Direct Flight Muscle Formation

In *Drosophila*, DFM (steering muscles) develop from founder cells in the region of the wing imaginal disc (Ghazi *et al*., 2000; Kozopas and Nusse, 2002) (**Figure 5**). At about 36 h APF, clusters of *dumbfounded* (*duf*)-expressing cells gather and prefigure individual muscles. Duf, a fusion-promoting adhesion molecule in embryos, is required for the aggregation and fusion of DFM founder cells (Kozopas and Nusse, 2002). The *apterous* (*ap*) gene is also expressed in the small clusters of founder cells that will lead to the formation of the DFM myotubes (Ghazi *et al*., 2000). The *duf*- and *ap*-expressing cells are adjacent to cells expressing *Drosophila Wnt oncogene analog 2* (*D-Wnt-2*) that likely give rise to DFM attachment sites (see Section 2.2.3.3.2).

Kozopas and Nusse (2002) proposed that each adult DFM uses a group of *duf*-expressing cells to act as "cofounders." Cofounders may pass muscle identity to feeder cells by activating genes encoding transcription factors. Each cofounder cell helps seed the syncytial growth of the muscle that will take on the shared identity of the entire founder group.

2.2.2.7. Jump Muscle

The jump muscle (TDT) of *Drosophila* is formed adjacent to the DVM (see Section 2.2.1.2). It is composed of 30 fibers that extend from the trocanteral segment of the leg to the dorsal notum (**Figure 1**). The TDT arises *de novo* and does not use larval scaffolds (Rivlin *et al*., 2000). Rivlin *et al.* (2000) found that, as in DVM, there are two separate pools of myoblasts: one pool, the IPs, serve a muscle founder cell role, while the other pool (feeder cells) gives rise to myoblasts that will fuse with IPs. The IPs arise from myoblasts on the leg imaginal disc. Most myoblast feeder cells have small nuclei (2–3 μm) and are seen on the outermost edge of the developing TDT. At 4 h APF, 12 or 13 TDT IPs line up parallel to one another, take up the position of the adult fiber, elongate, and extend dorsoventrally. The number of IPs stays constant during the rest of development. At 20–24 h APF, there is an array of

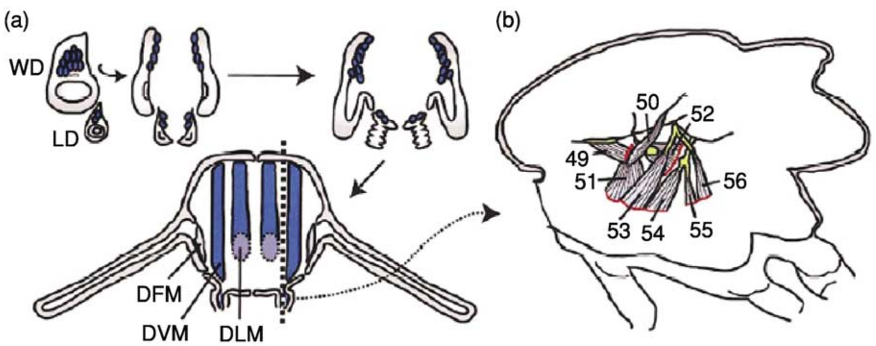

Figure 5 *Drosophila* direct flight muscles (DFM) arise from wing disc-associated myoblasts. (a) Myoblasts associated with the wing disc (WD) and the leg disc (LD) are shown in blue. The DFM develop in the region of the wing hinge. (b) Sagittal view of an adult thorax showing the DFM. The dorsal attachment site of each muscle is shown in yellow, the ventral attachment site is shown in red. Muscles are numbered according to Miller (1950). DLM, dorsolongitudinal muscles; DVM, dorsoventgal muscles. (Reprinted with permission from Kozopas, K.M., Nusse, R., **2002**. Direct flight muscles in *Drosophila* develop from cells with characteristics of founders and depend on DWnt-2 for their correct patterning. *Devel. Biol. 243*, 312–325; © Elsevier.)

thin fibers surrounding a core of myoblasts. The authors concluded that TDT IPs are very similar to the muscle pioneers of the grasshopper embryo.

2.2.2.8. Leg Muscle

During metamorphosis, the larval thoracic legs of *Manduca* are replaced by a new set of adult legs (Consoulas and Levine, 1997). Unlike *Drosophila*, *Manduca* has no true leg imaginal discs. Consoulas and Levine (1997) investigated leg development using various stains to identify proliferating and differentiating cells. Larval leg muscles are among the first muscles to degenerate during the larval-to-pupal transition, possibly by apoptosis. There was no evidence of surviving larval muscles or nuclei, and it is unlikely that myoblasts arising from degenerating larval muscle contribute to adult leg formation. Instead, myoblasts that are formed in the larvae undergo rapid proliferation at the late larval stage, and aggregate to form adult muscle anlage at specific production sites. These new myoblasts are associated with the peripheral nerves and imaginal tracheae that may guide their migration to development sites. As the larval muscles degenerate, the new myoblasts form spindle-shaped cells that proliferate, fuse, and differentiate into myotubes early in the pupal stage. The study concluded that most, if not all, of the imaginal muscles are generated *de novo* without the involvement of larval elements.

2.2.2.9. Inductive Mechanisms

2.2.2.9.1. Nervous system The influence of nerves on adult myogenesis (see **Chapter 2.3**) is in stark contrast to embryogenesis where the formation of larval muscle is independent of innervation (Broadie and Bate, 1993; Consoulas *et al*., 2000; **Chapter 2.1**). Fernandes and Keshishian (1998) examined the interactions between differentiating nerves and the two sets of flight muscles during *Drosophila* pupal metamorphosis. They eliminated synaptic interactions during formation of the IFM by cutting motor nerves at different locations using laser ablation. Denervation was found to cause an overall decrease in the size of the myoblast pool. DVM formation was dramatically inhibited. Fusion of myoblasts was not completely abolished, but denervation prevented the complete formation of the mature fiber. One possibility suggested by the authors is that IPs likely do not form. The adult muscles that use larval muscle fibers as myoblast fusion targets (DLM) still developed, but the fibers were smaller, probably due to fewer myoblasts fusing or to a delay in myoblast fusion. The results suggested that both nerves and larval scaffolds influence fusion. However, when the larval muscle precursors were ablated in conjunction with nerve severance, the DLM showed an absolute dependence on the motor neurons for their formation. The authors concluded that the size of the myoblast pool and early events in fiber formation depend on the presence of the nerve, which perhaps supplies a nerve-derived proliferation factor.

Manduca has been especially useful for the study of nerve–muscle interactions because most motor neurons that innervate the newly formed adult muscles are respecified larval motor neurons, and adult muscle development occurs in constant proximity of the motor neuron endings (Kent and Levine, 1988). Bayline *et al*. (2001) found that *Manduca* DLM failed to develop following complete denervation because myoblasts failed to accumulate in the DLM anlage. Each of the five fiber bundles is innervated by a separate motor neuron. When four of the five neurons were severed, the nerve to the fifth muscle, MN5, remained specific to it and did not rescue the other four fibers. Myoblast accumulation, but not myonuclear proliferation, increased around the MN5 terminals producing a hypertrophied adult DLM5 (Bayline *et al*., 2001). Therefore, motor neurons compete for uncommitted myoblasts. Myoblast accumulation in the DLM anlage requires innervation, and individual muscle fiber bundles require specific innervations for their development.

A nerve–muscle co-culture system was used to investigate critical nerve–muscle interactions during development in *M. sexta* (Luedeman and Levine, 1996). Muscle precursor cells derived from the developing thoracic legs of early pupae were cultured in the presence of neurons. Interestingly, contractile myotubes did not form when muscle precursors cells were cultured alone. Live neurons were also needed, but, as suggested by the lack of an effect by tetrodotoxin, these did not need to be electrically active. Bromodeoxyuridine (BrdU) studies suggested that the co-cultured neurons promoted the proliferation of myogenic cells. Steroid hormone (20E), on the other hand, also enhanced BrdU incorporation into nuclei of myogenic cells, even in the absence of neurons. The results suggest that both neurons and ecdysteroids (see Section 2.2.2.9.2) play an important regulatory role in adult muscle development, in part by enhancing the proliferation of myogenic cells.

Consoulas and Levine (1997) also investigated the influence of nerves on *Manduca* leg muscle precursors. Adult legs form from myoblasts that originate in production sites located within the legs, and migrate to the sites of muscle formation where they accumulate, proliferate, and fuse to form muscle

fibers. Cutting of the larval leg nerves prior to metamorphosis resulted in the myoblasts failing to accumulate in the appropriate regions of the leg. The myoblasts did not die, but remained in the denervated legs as dispersed cells or as aggregates in inappropriate regions. When the legs were denervated after the myoblasts had aggregated, myoblast proliferation was reduced but differentiation continued (**Figure 6**). Thus, motor nerves are essential for determining both the accumulation of myoblasts into the correct areas of muscle development and the level of myoblast proliferation (Consoulas and Levine, 1997).

2.2.2.9.2. Hormones Hormones exert control over most developmental processes during metamorphosis. Ecdysone (20E) and JH are the most studied hormones, primarily in *M. sexta* (Weeks and Truman, 1986a, 1986b; review: Truman and Riddiford, 2002; **Chapters 3.5** and **3.7**). 20E is a steroid hormone released from the prothoracic gland in *Manduca* and the ring gland in *Drosophila* prior to larval molts and metamorphosis (Hegstrom *et al.*, 1998; **Chapters 3.2** and **3.3**). It interacts with at least two isoforms of ecdysone receptors (EcR), EcR-A and EcR-B1, in *Manduca*, or three isoforms, EcR-A, EcR-B1, and EcR-B2, in *Drosophila* (see **Chapter 3.5**).

During the last larval instar in *Manduca*, a small peak of ecdysteroids commits the larva to pupal differentiation (Riddiford, 1976). This peak is followed by a larger, prepupal peak that promotes molting to the pupal stage. After pupal ecdysis, there is a large release of steroids, the adult peak, which regulates the development of the adult moth. The fall of ecdysteroid titer later in adult development leads to reduced growth of the flight muscle. Shortly before eclosion, the flight muscle becomes unresponsive to these hormones (Tischler *et al.*, 1989). Other muscles respond differently to the peaks, in ways that are partially dependent on the receptor isoform expressed in the muscle.

In the *Manduca* muscle, the selection of EcR isoforms during metamorphosis is regulated by the motor neurons innervating the muscle. The subsequent release of ecysteroids determines the nature of the response in the muscle. For example, Hegstrom *et al.* (1998) followed the remodeling of the larval dorsal external oblique 1 (DEO1) muscle, which consists of five fibers, over the course of metamorphosis. Four of these fibers degenerate, while the remaining one participates in regrowth (nuclear proliferation) of the dorsal external five (DE5) muscle of the adult. Degeneration of the four fibers correlates with expression of only EcR-A in them just prior to pupal ecdysis followed by low levels of both EcR-A and EcR-B1 shortly after pupation. The fifth fiber shows upregulation of EcR-B1 3 days after pupal ecdysis. It is also the only one that stays innervated. Thus, the fate of the muscle DEO1 is determined by interactions between rising and falling ecdysteroid titers, the pattern of specific EcR isoform expression, and the interactions with other cells in the local environment (Hegstrom and Truman, 1996; Hegstrom *et al.*, 1998). In *Drosophila*, larval muscle cells express mostly EcR-B1, while imaginal discs and the proliferation zones express EcR-A.

20E regulates the function of *Broad-Complex* (*BR-C*) (as well as other ecdysone responsive genes) (Restifo and White, 1992). The *BR-C* locus encodes a family of zinc finger containing transcription factors (review: Riddiford *et al.*, 2003). Mutations in these genes, which belong to *reduced bristles on palpus* (*rbp*) class, have differential effects on flight muscle development (see Section 2.2.3.3.2).

2.2.3. Muscle Differentiation

2.2.3.1. General Features Established by the Early Studies

Research in flight muscle development in Diptera dates back over 100 years. A major area of study in the early and mid twentieth century focused on the description of ultrastructural changes that take place in the developing flight muscle cell using light microscopy and EM (e.g., Gregory *et al.*, 1968; Bursell, 1973; Valvassori *et al.*, 1978). EM analyses of the *Drosophila* IFM revealed a pattern of myofibril growth from the center, increasing in diameter by addition of peripheral myofilaments (Shafiq, 1963; Auber, 1969). Studies on *Calliphora* DLM, showed that no larval muscle myofibrils persisted in the adult muscle; instead, residual microtubules appeared to function as scaffolds for the assembly of new myofibrils (Crossley, 1972). The longitudinal growth of the DLM was proposed to occur by a mechanism whereby new sarcomeres were added by splitting of the Z bands, perhaps driven by tension from the guide (tendon) cells (Auber, 1969; Houlihan and Newton, 1979; review: Crossley, 1978). This was followed by a period where muscle length increased by lengthening of sarcomeres, a process that continued for several hours after eclosion and was believed to be driven by stretching of the muscle in response to increased hemolymph pressure (Houlihan and Breckenridge, 1981). An alternative model of muscle growth, based on studies in the blowfly *Lucilia cuprina* flight muscle,

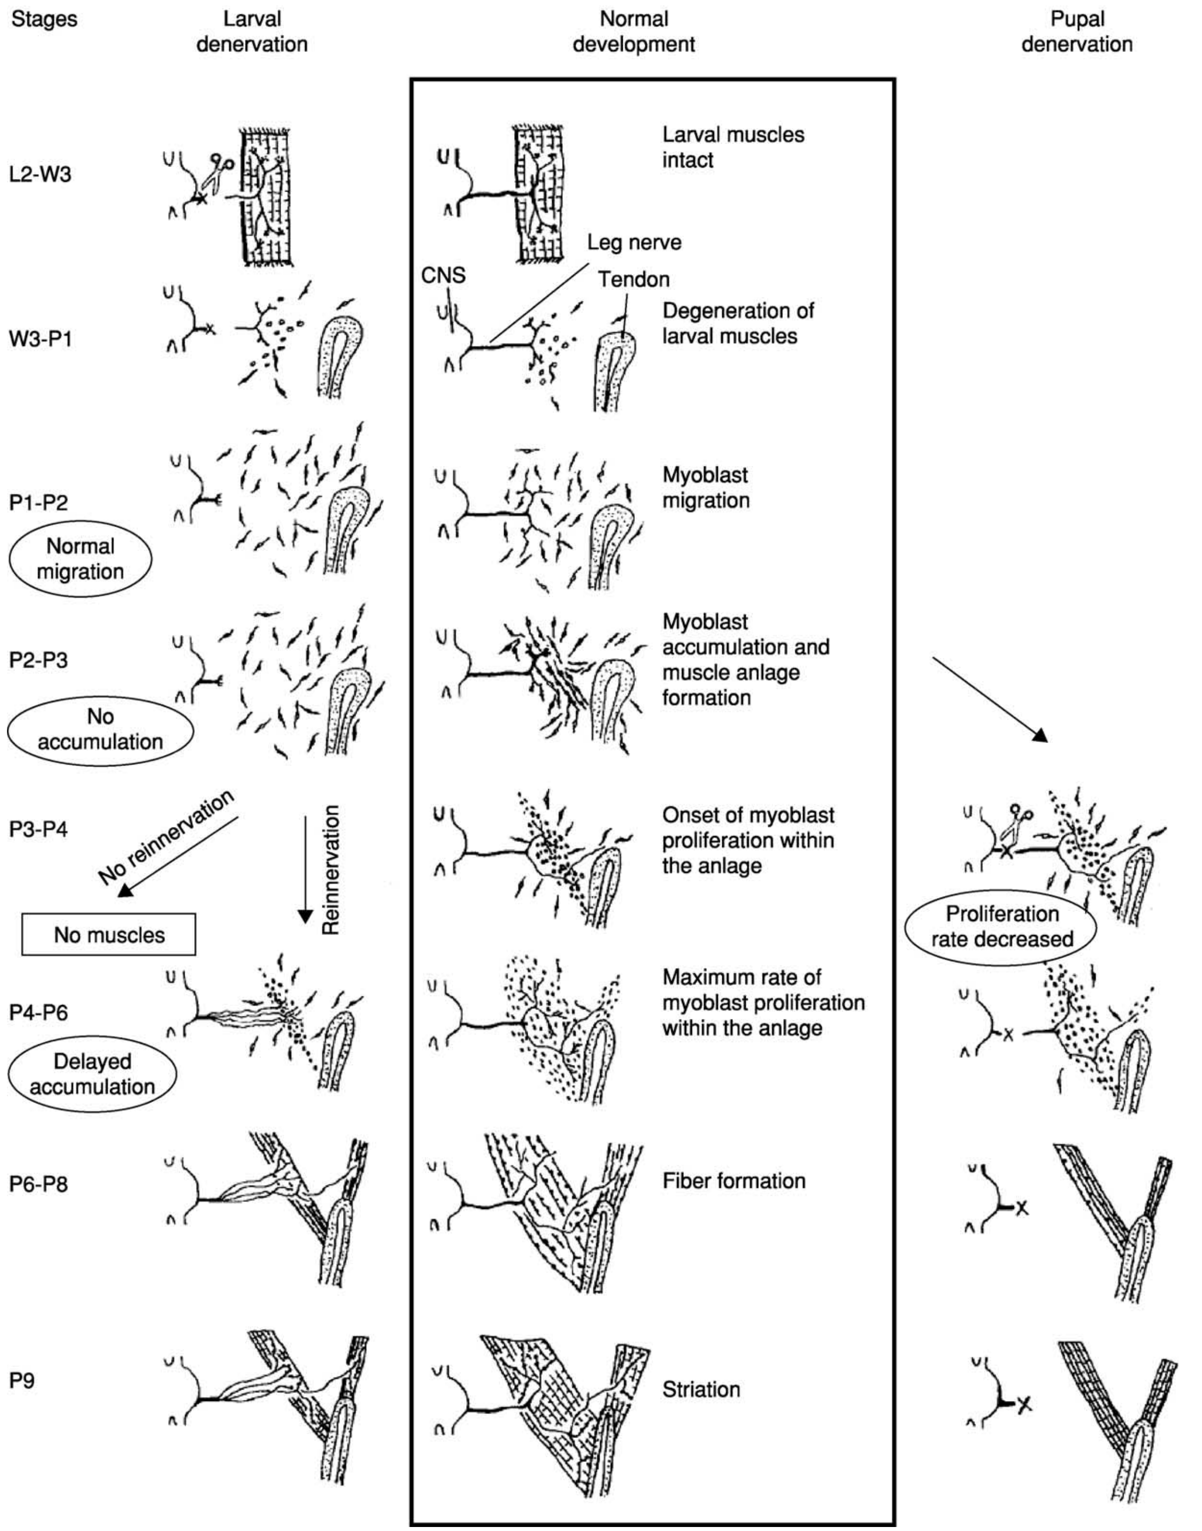

Figure 6 Development of adult leg muscle in *Manduca*. The association between nerves and developing muscles is depicted in the central panel. The effect of denervation prior to metamorphosis is shown on the left panel, and the effect after metamorphosis is shown on the right panel. Muscles do not form when denervation is performed in the larval stage because myoblasts fail to aggregate and proliferate in the areas of adult muscle formation associated with the developing tendon. Denervation in the pupal stage reduces the rate of myoblast proliferation and results in the formation of smaller muscles. (Consoulas, C., Levine, R.B. **1997**. Accumulation and proliferation of adult leg muscle precursors in *Manduca* are dependent on innervation. *J. Neurobiol. 32*, 531–553; © John Wiley & Sons, Inc., Reprinted with permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.)

stipulated addition of sarcomeres at the terminal ends of the myofibril (Peristianis and Gregory, 1971). Electron-dense bodies (similar to the "Z bodies" described in *Drosophila* by Shafiq (1963)) were found in close association with microtubules near the sarcolemma. These bodies appear to split while retaining the attached myofibrils that could serve as "seeds" for new myofibrils.

A significant development in the early 1970s was the implementation of genetic screens to identify flightless *Drosophila* mutants. It was not until the advent of recombinant DNA technology in the 1980s that many of the mutant gene products were identified as contractile proteins (e.g., actin, myosin, and troponin T) and DNA binding proteins (e.g., *erect wing* and *stripe*) (Koana and Hotta, 1978; Deak *et al*., 1982; reviews: Bernstein *et al*., 1993; Vigoreaux, 2001). This combined molecular–genetic approach fueled a major wave of research into muscle development and function that has continued until this date.

2.2.3.2. Expression of Muscle Structural Protein Genes

The myofibril is a structural complex of 20 or so proteins organized into separate but interacting filament systems and cross-linking structures (see Vigoreaux (2001) for a list of *Drosophila* IFM myofibrillar proteins) (**Table 3**). Coordinating the expression and assembly of contractile proteins can be achieved at multiple levels of regulation. In *Drosophila*, the interaction between *trans* regulatory factors and *cis* regulatory DNA sequences has been examined for a handful of structural protein genes.

2.2.3.2.1. Transcriptional regulation In *Drosophila*, actin is encoded by six genes that display temporal and tissue specific patterns of expression (Fyrberg *et al*., 1983). Two of the genes, *Act79B* and *Act88F*, have been shown by *in situ* hybridization and by fusion of DNA regulatory sequences to reporter genes (e.g., encoding β-galactosidase or green fluorescent protein (GFP)) to be expressed primarily in adult muscles. *Act88F* encodes the main actin isoform of the IFM and *Act79B* encodes the main isoform of tubular muscles found in the leg and the thorax (Sanchez *et al*., 1983; Courchesne-Smith and Tobin, 1989). *Cis* regulatory sequences that confer tissue specificity to *Act79B* are located within 4 kb of the 5′ flanking DNA. Tissue-specific expression of *Act88F* is also provided by sequences close to the point of transcription initiation (Geyer and Fyrberg, 1986; Hiromi *et al*., 1986). Wild-type levels of *Act88F* mRNA accumulation during flight muscle development are obtained when ~1 kb immediately 5′ of the transcription initiation site is present; derivatives retaining 600 or fewer base pairs of flanking DNA do not accumulate detectable levels of mRNA.

The specific regulatory sequences have not been delineated but it is intriguing that the *Act88F* promoter lacks D-Mef2 binding sites (Geyer and Fyrberg, 1986). D-Mef2 is a known transactivator of muscle-specific differentiation genes whose expression persists in adult muscle fibers (Bour *et al*., 1995; Roy and VijayRaghavan, 1999), and many of the genes expressed in differentiated adult muscles (e.g., those encoding myosin heavy chain and troponin T) have one or more pairs of D-Mef2 binding sites (Arbeitman *et al*., 2002). A small number of *D-mef2 trans* heterozygote mutant adults have defects in their IFM and fail to fly (Ranganayakulu *et al*., 1995). Moreover, it is known that misexpression of *D-mef2* in nonmesodermal tissue results in transcription of contractile protein genes (Lin *et al*., 1997). Thus, this transcription factor is likely to be required for normal expression of some IFM genes.

In addition to the IFM, *Act88F* is expressed at very low levels in other muscles, including muscles in the leg (Roy and VijayRaghavan, 1997; Nongthomba *et al*., 2001). The same promoter construct (~1.8 kb of 5′ flanking DNA) drives *Act88F* expression in IFM and the other muscles. It remains to be established whether the same or different *cis* regulatory elements are functional in individual muscle groups that express *Act88F*.

Homologs of the *Act79B* (*ActD1*) and *Act88F* (*ActE2*) genes in the closely related *Drosophila virilis* species show expression patterns similar to those described for *D. melanogaster* (Lovato *et al*., 2001). In *D. virilis*, *ActD1* is predominantly expressed in the jump muscle and in some muscles in the thorax and leg. *ActE2* is predominantly expressed in the IFM and in some tubular muscles of the leg (Lovato *et al*., 2001). *ActE1*, the homolog of *D. melanogaster Act87E*, is expressed in the tubular muscles of the ventral thorax and leg, and at low levels in the TDT, suggesting that some tubular muscles express more than one actin isoform. Comparison of the 5′ flanking sequences between *D. virilis* and *D. melanogaster* should facilitate identification of *cis* regulatory elements that confer tissue and temporal specificity. One such comparison conducted for the *troponin T* (*TnT*) genes identified several conserved sequences in the region immediately upstream of the transcription initiation sites (Benoist *et al*., 1998).

Like actin, troponin C (TnC) is also encoded by a multigene family in *D. melanogaster*. The expression of the four *TnC* genes is developmentally regulated and one gene (*TnC41C*, renamed *DmTnC1*) is expressed exclusively in adult muscles (Fyrberg

Table 3 Genes encoding structural proteins of *Drosophila* adult leg and flight muscle myofibrils

Structure/gene	*Description*	*Properties*	*References*
Connecting filament			
sallimus	Encodes several isoforms of large modular proteins including kettin and a titin-like protein	Component of connecting filaments in IFM that impart passive stiffness; possible role in the assembly of the terminal Z disc in IFM	Hakeda *et al.* (2000), Machado and Andrew (2000), Kolmerer *et al.* (2000)
bent	Encodes different size variants of projectin that also differ in their sarcomeric distribution in leg and IFM	Component of connecting filaments in IFM that impart passive stiffness; role in development not known	Vigoreaux *et al.* (1991), Ayme-Southgate *et al.* (1995), Fyrberg *et al.* (1992)
Thick filaments			
Myosin heavy chain	Encodes myosin heavy chain and myosin rod protein	Alternative splicing generates different isoforms in leg and IFM; transcription from intronic promoter generates shorter myosin rod protein in DFM; myosin heavy chain essential for thick filament assembly	Swank *et al.* (2000), Standiford *et al.* (1997)
Paramyosin	Encodes paramyosin and mini-paramyosin	Transcription from intronic promoter generates shorter mini-paramyosin. Phosporylation may modulate role in myofilament assembly	Becker *et al.* (1992), Vinos *et al.* (1992)
Stretchin-Mlck	Alternative splicing generates variants with and without myosin light chain kinase domain.	At least one isoform (myostrandin/A225) expressed in IFM	Champagne *et al.* (2000), Patel and Saide (2003)
Myosin light chain 2	Encodes myosin regulatory light chain	Wild-type MLC-2 stoichiometry is required for normal IFM myofibril assembly and function	Warmke *et al.* (1992)
Myosin light chain 1	Encodes myosin essential (alkali) light chain	IFM-specific isoform generated by alternative splicing	Falkenthal *et al.* (1987)
flightin	Encodes flightin strictly in IFM	IFM devoid of flightin assembles longer than normal thick filaments	Reedy *et al.* (2000)
Thin filaments			
sanpodo	Encodes tropomodulin	Involved in thin filament length determination in IFM	Mardahl-Dumesnil and Fowler (2001)
Actin 79B	Encodes a tubular muscle actin	Likely critical for thin filament assembly in leg but not formally tested	Courchesne-Smith and Tobin (1989)
Actin 88F	Encodes IFM actin and arthrin	Essential for thin filament and Z band assembly in IFM	Hiromi and Hotta (1985), Beall *et al.* (1989)
upheld	Encodes troponin T	Required for myofibril integrity	Fyrberg *et al.* (1990a)
wings up A	Encodes troponin I	Alternative splicing generates multiple isoforms in IFM and leg muscles. Absence in IFM prevents sarcomere formation	Beall and Fyrberg (1991)
Troponin C 41F	Encodes major IFM isoform. Separate genes encode minor IFM isoform and other muscle isoforms	No role in development known	Qiu *et al.* (2003)
Tropomyosin 1	Encodes standard muscle and cytoplasmic tropomyosin and two IFM-specific troponin H isoforms	TnH haploidy does not affect myofibril assembly	Kreuz *et al.* (1996)
Tropomyosin 2	Encodes standard muscle tropomyosin expressed in IFM, TDT, and other muscles	Absence results in structurally weaker myofibrils in IFM	Kreuz *et al.* (1996)
Glutathione-S-*transferase S1*	Encodes glutathione-*S*-transferase	Expressed in IFM but not other muscles. No role in development known	Clayton *et al.* (1998)
Z bands			
α actinin	Encodes different α-actinin size isoforms by alternative splicing	Same isoform expressed in leg and IFM; role in Z band and terminal insertion sites	Fyrberg *et al.* (1990b)
Unknown	Encodes Z(210)/zetalin	Expression limited to IFM and large cells of the jump muscle	Vigoreaux *et al.* (1991)

IFM, indirect flight muscles; DFM, direct flight muscles; TDT, tergal depressor of trochanter.

et al., 1994; Qiu *et al*., 2003) (**Table 3**). Two isoforms are expressed in the IFM; the major isoform (encoded by *DmTnC4*) differs from all others by having one instead of two calcium binding sites. This isoform is also expressed at high levels in the asynchronous IFM of the waterbug *Lethocerus* and the mosquito *Anopheles gambiae* (Qiu *et al*., 2003).

All muscle myosin heavy chains (MHC) in *D. melanogaster* are encoded by a single gene that undergoes alternative splicing of RNA transcripts to generate tissue-specific isoforms (reviews: Bernstein *et al*., 1993; Swank *et al*., 2000). A *Mhc* transgene containing 9 kb of flanking DNA at the 5′ and 3′ end is sufficient to dictate expression of this gene in all muscles and correct all defects engendered by *Mhc* amorphic alleles (Cripps *et al*., 1994). Nevertheless, as little as 400 base pairs of upstream sequence is required for transcription if the first intron is included. The first intron also contains a controlling element that is involved in IFM expression (Hess *et al*., 1989; Swank *et al*., 2000). Similarly, the first intron of the *Act88F* gene contains DNA sequences involved in temporal regulation (Fyrberg *et al*., 1998).

There are two genes encoding tropomyosin (TM) in *D. melanogaster*: the *TmI* gene (also called *Tm2*) encodes standard muscle TM, and *TmII* (also called *Tm1*) encodes muscle and cytoplasmic TM and the functionally distinct, IFM-specific TM fusion protein known as troponin H (TnH) (Karlik and Fyrberg, 1986; Hanke and Storti, 1988) (**Table 3**). IFM and TDT controlling elements are found in the proximal muscle enhancer located within the first intron of the *TMI* gene (Schultz *et al*., 1991; Lin and Storti, 1997). Putative Mef2 binding sites and a basal level muscle activator region adjoining this enhancer element are required for high level expression in TDT and IFM. Transcriptional regulatory elements also reside within the first intron of the *TmII* gene (Bernstein *et al*., 1993; Meredith and Storti, 1993). In fact, many contractile protein genes in *Drosophila* have introns close to the transcription initiation site, but the extent to which intronic sequences dictate tissue and developmental regulation has not been fully examined.

Like *TmII*, there are several other genes in *Drosophila* that encode more than one type of protein through the use of alternative promoters and/or alternative splicing (**Table 3**). Myosin rod protein (MRP) mRNA, for example, is transcribed from a promoter located within intron 12 of the *Mhc* gene (Standiford *et al*., 1997). MRP shares the same sequence as the MHC except for the first 77 amino acids (Standiford *et al*., 1997). The tissue distribution of MRP is distinct from that of MHC suggesting that the two promoters are regulated independently. Miniparamyosin (mPM) mRNA, on the other hand, is transcribed from a promoter within intron 7 of the paramyosin (*Pm*) gene (Maroto *et al*., 1995). Both proteins are expressed in adult tubular and flight muscles albeit at different ratios depending on the muscle type (see Section 2.2.3.3.3). The *mPm* and *Pm* promoters are regulated independently (Becker *et al*., 1992; Maroto *et al*., 1995; Arredondo *et al*., 2001a). Arredondo *et al*. (2001a) have shown that a Mef2 site in the *Pm* promoter appears not to be important for high expression in adult muscles but to be required for tissue specificity. The *mPm* promoter lacks consensus binding sites for known muscle transcription factors (Becker *et al*., 1992; Maroto *et al*., 1995; Arredondo *et al*., 2001a). Comparison of the upstream sequence of the *mPm* transcription unit between *D. melanogaster* and *D. virilis* revealed three conserved regions in sequence and position, at least one of which regulates *mPm* transcription in adult muscles (Arredondo *et al*., 2001a). Nevertheless, these studies did not uncover *cis*-acting elements that regulate IFM expression within the 4 kb upstream of the transcription start site.

A *D. melanogaster* gene at 62C (known as *sallimus*, *kettin*, or *D-titin*) encodes titin and several isoforms of the related protein kettin (Kolmerer *et al*., 2000; Zhang *et al*., 2000). The two proteins share the same N-terminal sequence but kettin is about one-third shorter than titin. The mechanism that gives rise to these different proteins, presumably alternative splicing or differential termination, has not been elucidated.

Unfortunately, progress in the understanding of the transcriptional regulation of individual genes has not translated into an understanding of the mechanisms controlling myofibril assembly. The *Act88F* promoter is activated very early in pupal development, approximately 16 h APF (Fernandes *et al*., 1991), or 10 h before activation of *Mhc* or any other known myofibrillar protein gene examined to date (**Table 2**). It is not yet known how the rates of actin expression correlate with the rates of actin polymerization *in vivo* but the early activation of actin gene transcription suggests that thin filament assembly may be a critical event in the initiation of myofibrillogenesis. On the other hand, studies of the thin filament pointed end capping protein tropomodulin (TMOD) are more consistent with the view that thin filament assembly is subservant to thick filament assembly (see Section 2.2.3.3.1).

Only a few studies have examined the transcriptional activation of contractile protein genes during

development of a particular muscle type. Western blot analysis of developing IFM showed that the IFM-specific protein flightin (FLN) is first detected about 60 h APF, well after thick filaments have begun to assemble and align transversely with interdigitating thin filaments (Vigoreaux *et al.*, 1993). At this time, another thick filament accessory protein, A225, and the Z band protein Z(210) are first detected (Patel and Saide, 2003; Vigoreaux, unpublished data). The transcript encoding myosin essential (alkali) light chain (ELC) is absent in early pupal stages but detected in mid-pupa (~48 h APF) onward (Falkenthal *et al.*, 1984). Finally, Northern blot analysis of total animal RNA showed that *Pm* and *mPm* gene transcripts, which are expressed in several muscles of the adult, are absent 12–14 h APF but present at 75 h APF (Becker *et al.*, 1992). In lepidopteran tubular (synchronous) muscle, PM appears before MHC (Lehmann, 1984). Additional studies that examine the temporal accumulation of other contractile proteins or their transcripts are needed in order to uncover the broad rules that govern the transcriptional control of myofibril assembly.

Genomic approaches are currently employed for the study of muscle development, but the benefits from this type of global approach have yet to fully materialize. White *et al.* (1999) used DNA microarrays to analyze the expression of genes during metamorphosis in *Drosophila* and found that many of the genes encoding contractile proteins are not activated until more than 12 h APF. This study relied on whole-animal RNA and did not differentiate among the adult muscle types (White *et al.*, 1999). A follow-up microarray study identified a subset enriched for genes expressed in terminally differentiated muscle (Arbeitman *et al.*, 2002). The peak expression pattern of these genes at late pupal stages was preceded by a peak in the expression of *D-mef2*, which in turn, was preceded by peak expression of *twist*. Thus, the study showed the potential of the microarray approach to reveal a muscle regulatory hierarchy.

Other large-scale functional genomic approaches such as insertional mutagenesis and enhancer detection systems that are operational in a variety of insects could also prove highly beneficial for the study of muscle development (Horn *et al.*, 2003). Finally, experimental approaches that rely on genomic or proteomic platforms applied to individual tissues (e.g., IFM) are likely to be most informative in deciphering how the assembly of contractile proteins is orchestrated during muscle development.

In summary, there is a dearth of information regarding the role of transcriptional activation as a control mechanism for coordinating the *in vivo* assembly of contractile proteins. In this regard, continuing and future studies with transgenic *Drosophila* should be informative. For example, expression of a *flightin* (*fln*) transgene regulated by the *Act88F* promoter does not appear to alter the timing of Flightin (FLN) expression or interfere with myofibril assembly (Barton *et al.*, 2002). Thus, other, posttranscriptional regulatory mechanisms must be considered.

2.2.3.2.2. Posttranscriptional regulation Five of the 19 exons of the *Drosophila Mhc* gene (exons 3, 7, 9, 11, and 15) are alternatively spliced to produce multiple forms of the protein in different muscles (reviews: Bernstein *et al.*, 1993; Swank *et al.*, 2000). Standiford *et al.* (2001) identified three conserved intronic elements that function in combination with nonconsensus splice donor sequences to control splicing of the IFM-specific exon 11e. One element acts as a splice repressor while the other two behave as splice enhancers (Standiford *et al.*, 2001).

The significance of alternative splicing is highlighted by studies of mutations that interfere with the tissue-specific splicing of an alternative exon. One example is Mhc^{10}, a mutation that blocks the splicing of alternative exon 15a and compromises the assembly of thick filaments in IFM and TDT but not in muscles that do not use this exon (Collier *et al.*, 1990). Differences in the mechanisms of tissue-specific splicing are also evident by mutations such as Mhc^{11}. This mutation affects the 5′ splice site of exon 9a by blocking the expression of correctly spliced transcripts containing this exon in the IFM and TDT (Kronert *et al.*, 1991). While the IFM produces an aberrantly spliced transcript (containing exons 9a, 9b, and 9c), which does not produce a protein, the TDT substitutes exon 9b for 9a, resulting in normal levels of myosin and a functional jump muscle.

Drosophila ELC transcripts are also alternatively spliced in a tissue-specific fashion (Falkenthal *et al.*, 1987). IFM is the only tissue in the adult that accumulates an alternatively spliced mRNA that lacks exon 5, resulting in a protein with a unique C-terminal tail of 14 amino acids. The choice between splicing pathways involves the use of a nonconsensus 3′ splice junction in larvae and in the tubular muscles of adults, whereas in the IFM only consensus splicing sequences are utilized. The *TmI* gene of *Drosophila* also relies on 3′ alternative splicing to produce two different TM polypeptides that differ in their C-terminal 27 amino acids. One of the transcripts encodes flight and jump muscle TM (Basi *et al.*, 1984; Basi and Storti, 1986). The *Drosophila TnT* gene also undergoes tissue-specific

splicing resulting in the generation of one variant that is unique to the IFM and TDT (Benoist *et al.*, 1998).

While most examples of alternative splicing have been shown to generate tissue-specific isoforms, there are cases in which differential splicing occurs in the same tissue. One such case involves the *Drosophila TmII* gene whose alternative splicing at the 3′ end generates the IFM-specific proteins TnH-33 and TnH-34. Three kettin isoforms, possibly arising from alternative splicing, have been also detected in *Drosophila* IFM myofibrils (Kulke *et al.*, 2001), while different size variants are also evident in *Lethocerus* flight and leg muscle (Lakey *et al.*, 1990). Finally, different patterns of alternative splicing of TnT in the flight muscle have been shown to occur in separate populations of dragonflies (Marden *et al.*, 2001). These differences impact flight muscle contractile performance and are likely to manifest complex ecological behaviors. The functional role, if any, of kettin, TnH, and TnT isoforms on myofibril development is not known.

To summarize, the muscle-specific expression of contractile protein genes is under complex regulation. The regulatory factors (transcription factors, splicing factors) responsible for tissue specificity have not been identified. Other types of posttranscriptional control mechanisms (e.g., translational control, regulated proteolysis) are possible but evidence in support of these mechanisms has not been uncovered.

2.2.3.2.3. Protein modifications and muscle-specific variants Many myofibrillar proteins are posttranslationally modified, but the potential role of these modifications in development is largely unexplored. Dramatic changes in IFM protein phosphorylation occur during the pupal to adult transition in *Drosophila*. Myosin regulatory light chain (RLC) and FLN have been shown to undergo multiple phosphorylations during the final stages of IFM development, at or near eclosion (Takano-Ohmuro *et al.*, 1990; Vigoreaux and Perry, 1994). Replacement of two RLC serines that are phosphorylated by myosin light chain kinase (MLCK) with alanines had no effect on myofibrillogenesis (Tohtong *et al.*, 1995; Dickinson *et al.*, 1997). Furthermore, heterozygotes for a deficiency that deletes the *mlck* gene fly normally suggesting that phosphorylation of the two RLC serine residues has no role in development (Tohtong *et al.*, 1997).

In contrast to RLC and FLN, mPM and PM undergo dephosphorylation during the transition from late stage pupa to flying adult (Maroto *et al.*, 1996). Overexpression of mPM does not affect its phosporylation profile (Arredondo *et al.*, 2001b). Changes in TnT phosphorylation have been documented to occur during the final stages of *Drosophila* flight muscle development (Benoist *et al.*, 1998; Domingo *et al.*, 1998). In the honeybee *Apis mellifera*, different molecular weight TnT bands are detected on sodium dodecylsulfate polyacrylamide gel electrophoresis (SDS-PAGE) of thorax proteins extracted from bees 1 day (nonflyers) and 5 days (flyers) after hatching (Domingo *et al.*, 1998). However, the functional significance of the above changes in the phosphorylation status of these proteins remains unclear.

To date, the only IFM protein kinases that have been identified are MLCK (Tohtong *et al.*, 1997) and projectin (Maroto *et al.*, 1992; Ayme-Southgate *et al.*, 1995). Neither protein kinase has been shown to be directly involved in muscle development. In vertebrates, titin kinase (Mayans *et al.*, 1998) and titin phosphorylation (Gautel *et al.*, 1993) have been shown to play a role in myofibrillogenesis. In *Drosophila*, however, the *titin* gene lacks kinase encoding sequences (Zhang *et al.*, 2000).

Studies *in vitro* have shown that the phosphorylation status of projectin affects the type of filaments formed by purified myosin and paramyosin. When autophosphorylated projectin from flight muscle of the locust *Locusta migratoria* is added to myosin and paramyosin, subfilament-like structures 7–10 nm in diameter are preferentially formed, instead of the 20–50 nm filaments that are formed in the presence of unphosphorylated projectin (Fahrmann *et al.*, 2002). On the other hand, heterozygotes of the *Drosophila* projectin mutant *bent*$^{\mathrm{Dominant}}$, which express ~20% truncated projectin missing the kinase domain, do not exhibit any muscle defects (Moore *et al.*, 1999).

Other protein modificiations, such as ubiquitination of actin to generate arthrin, occur during myofibril assembly (Ball *et al.*, 1987). The stoichiometry of arthrin to actin in *Lethocerus* IFM (1 : 6) suggests that there is one arthrin molecule for each TM–TN complex. The appearance of arthrin after TM and TN during *Drosophila* development is consistent with the TM–TN complex determining which actin subunit is targeted for conjugation with ubiquitin. *Drosophila* actin is also N-terminally processed by the product of the *modification* (*mod*) gene which is likely responsible for removing the *N*-acetyl-cysteine residue. Fly strains that are *mod*$^{-}$ have flight defects but their flight muscles are structurally normal, suggesting that absence of this posttranslational modification has no effect on actin polymerization or assembly (Schmitz *et al.*, 2000).

2.2.3.3. Ultrastructure of the Developing Muscle

2.2.3.3.1. Myofibril assembly The ultrastructural changes that take place during myofibril formation have been described for *Drosophila* DLM. Using EM, Reedy and Beall showed that the number of sarcomeres in each myofibril is determined early in development and remains constant throughout (Reedy and Beall, 1993a). This is in contrast to earlier studies in *Calliphora*, which showed the number of sarcomeres to be increasing during the early pupal stages (Houlihan and Newton, 1979). In the latter case, initial myofibrils (~42 h APF) consist of ~310 sarcomeres with uniform length (~1.7 µm) and width (three or four thick filaments across). During the next 60 h, the length and width of sarcomeres (and thick and thin filaments) increases gradually and synchronously to a final length of ~3.2 µm and width of 32–35 thick filaments (**Table 2**). This is also in contrast to DLM development in *Pieris brassicae*, where lengthening of thick filaments does not occur (Cifuentes-Diaz, 1989).

Similar to the *Calliphora* and *Lucilia* flight muscle (Crossley, 1978), *Drosophila* myofibrils form within temporary scaffolds of microtubules that are disassembled shortly before eclosion but before the muscle reaches its final dimensions (Reedy and Beall, 1993a). Microtubules also are seen during myofibril assembly of the jump muscle, but they tend to associate more with the membrane of the SR than with the myofibril. The study by Reedy and Beall (1993a) did not reveal any evidence for sarcomere splitting at the Z band (as had been described for *Calliphora* by Houlihan and Newton, 1979), addition of new sarcomeres at the terminal ends, stress fiber-like assemblies, scattered or out-of-register myofilaments, or bundles of unincorporated thick or thin filaments. Instead, it has shown that there is consistent regularity in sarcomere dimensions throughout development, unlike in *Calliphora* where different length sarcomeres are found in the terminal and medial regions of the growing myofibril (Houlihan and Newton, 1979). Studies in *P. brassicae* also failed to provide evidence of Z band splitting as a mechanism for adding new sarcomeres (Cifuentes-Diaz, 1989).

It is not obvious from these studies how sarcomere assembly is initiated, only that thick and thin filaments appear simultaneously in interdigitating arrays. Nerves contact the periphery of the myotube at about the same time, but the influence of nerves on the initiation of myofibril assembly is not yet established. In *Manduca*, striations are detected on day 7 after pupation, coincident with the arrival of growing motor neurons at their attachment sites in muscle fibers (Duch *et al.*, 2000).

There is increasing evidence that accessory proteins are intimately involved in determining the precise and final length of thick and thin filaments in *Drosophila* IFM. TMOD, encoded by the *sanpodo* gene in *Drosophila*, participates in thin filament length determination, while the myosin rod binding protein FLN is required for proper thick filament length determination (Reedy *et al.*, 2000; Mardahl-Dumesnil and Fowler, 2001).

During IFM development, a 43 kDa isoform of TMOD acts as a dynamic cap allowing continuous elongation from the pointed end. Normally, a 45 kDa isoform of TMOD, which appears to be specific for the IFM, replaces the 43 kDa in the adult, after assembly is completed. When TMOD is transiently overexpressed during the pupal stages through the use of a heat shock inducible promoter, the 43kDa isoform behaves as a permanent cap, instead of a dynamic one, preventing core thin filaments from growing, even after TMOD expression returns to normal levels. Furthemore, the switch from the 43 kDa to the 45 kDa isoform fails to take place in pupae that have been heat shocked. The length of core thin filaments is established at the time the heat shock is applied, and the most deleterious effects are seen when heat shock induction is applied during mid-to-late myofibril assembly (day 3 late – day 4 early APF). While the growth of core thin filaments is arrested, sarcomere elongation, addition of peripheral thin filaments, and thick filament length are unaffected by overexpression of TMOD, and the resulting sarcomeres in adult IFM are of normal length (Mardahl-Dumesnil and Fowler, 2001).

The length of thick filaments is determined, at least in part, by the expression of FLN. In late stage pupa of the *fln* null, fln^0, thick filaments and sarcomeres appear, on average, longer than normal (Reedy *et al.*, 2000). Very long (~10 µm) thick filaments are also evident in the IFM of very young fln^0 adults. The longer than normal sarcomeres observed in fln^0 pupae are in contrast with the normal length sarcomeres observed in TMOD overexpressing flies. Together, the studies of fln^0 and TMOD overexpression suggest that thick filament length may be the primary determinant for sarcomere length in *Drosophila* IFM. Since thin filaments appear to grow longer in fln^0, it is possible that the length of thin filaments is established through coordinated interactions with the thick filament, perhaps by the myosin head or other thick-to-thin filament cross-connecting structures (Reedy *et al.*, 2000; Mardahl-Dumesnil and Fowler, 2001).

The gradual and incremental changes in thin and thick filament length during myofibril assembly in

Drosophila IFM are not consistent with the "molecular ruler" hypothesis that has been proposed for vertebrate skeletal muscles (Whiting *et al*., 1989; Gregorio *et al*., 1999). These latter muscles contain titin, a gigantic protein that spans one half of a sarcomere (from Z line to M line) and associates with numerous myofibrillar proteins (Gregorio *et al*., 1999). Evidence that titin is involved in vertebrate thick filament and sarcomere assembly comes from studies in which the myofibroblastic cell line BHK-21-Bi, which expresses a truncated titin, fails to assemble sarcomeres and lacks thick filaments (van der Ven *et al*., 2000). Although a titin/kettin-encoding gene has been identified in *Drosophila*, the existence of titin in the IFM remains controversial (Machado *et al*., 1998; Kulke *et al*., 2001). Mutations in the *Drosophila titin* gene result in defective myoblast fusion and abnormal myofilament organization in embryonic muscles (Machado and Andrew, 2000; Zhang *et al*., 2000), but the role of this protein in adult muscle development has not been explored.

The parallel increase in the length of thick and thin filaments suggests that interactions between myofilaments, whether via the myosin head, accessory cross-linking proteins, or auxiliary proteins, play a prominent role in establishing filament and sarcomere length. This is supported by the studies of contractile protein mutants described in the following sections. Thick filaments that assemble in the absence of thin filaments (i.e., null mutant for IFM actin) show hexagonal packing only near the M line but are otherwise disorganized (Beall *et al*., 1989). Likewise, in the absence of thick filaments (i.e., null mutant for IFM MHC), reasonably well-ordered thin filaments are observed that are anchored aperiodically within Z disc-type assemblies (Beall *et al*., 1989; O'Donnell *et al*., 1989; Bernstein *et al*., 1993). The broad picture that emerges from these studies is that thick filaments and thin filaments assemble simultaneously but independently of one another (Reedy and Beall, 1993a). However, the ordered interdigitation of precise length myofilaments into regular sarcomeric assemblies requires the presence of the myosin motor domain and possibly other protein components that interconnect thick filaments to thin filaments (Fyrberg and Beall, 1990).

Cripps *et al*. (1999) engineered a transgenic "headless" myosin (i.e., a myosin whose N-terminus is the RLC binding site) that was expressed in the IFM via the *Act88F* promoter. Some aspects of myofibril assembly (e.g., double hexagonal interdigitation of thick and thin filaments) were not perturbed but the overall sarcomere assembly was highly disrupted. The defects were more pronounced with a headless construct expressing the embryonic hinge region and C-terminus than with a headless construct expressing the corresponding adult hinge region and C-terminus (Cripps *et al*., 1999). The observed defects implicate the myosin head in myofibril assembly but leave open the question as to the precise mechanism by which the head exerts its effect. One possibility is that the presence of the head domain is required simply for proper spacing and/or alignment of thick and thin filaments. A second, not mutually exclusive, possibility is that contractile forces are required for some aspects of myofibril assembly (see Section 2.2.3.3.1.4). A mutant "dead-head" myosin, i.e., a myosin with normal motor structure that is biochemically incapacitated, may help to distinguish between these two possibilities. In conclusion, it remains an open question how myofilaments intercommunicate to achieve synchronous and incremental elongation throughout IFM development. Studies to date implicate the myosin motor domain and, possibly, accessory proteins such as FLN and TMOD.

The genetic analysis in *Drosophila* has contributed greatly to our understanding of muscle development. The following sections will summarize the key findings that have emerged from studies of different classes of muscle mutants. Two broad conclusions from these studies are: (1) certain defects are not uncovered by ultrastructural analysis of the developing muscle but reveal themselves after the mature muscle has engaged in contractile activity; and (2) the broad characterization of many of these mutants' effects has yet to uncover the mechanisms by which the mutations affect myofibril assembly.

2.2.3.3.1.1. Effect of alterations in protein stoichiometries It is not surprising that all loss-of-function mutant homozygotes of contractile proteins examined to date have an effect on muscle structure. These studies indicate that each protein plays a fundamental role in myofibril assembly that is distinct from its role in contractile mechanics (Vigoreaux, 2001).

IFM from actin null homozygotes lack thin filaments and fail to assemble Z bands, but contain well-aligned thick filaments (Beall *et al*., 1989; Fyrberg and Beall, 1990). Some missense mutations in actin, e.g., $Act88F^{V339I}$, likely cause protein instability as no actin or thin filaments are present in the muscle and no distinct muscle structure is formed (Drummond *et al*., 1991). Like the actin null $Act88F^{KM88}$, this mutant also interferes with the accumulation of other proteins (see below).

Analogously, IFM from *Mhc* null homozygotes (*Mhc*^{7}) lack thick filaments but show continuous arrays of thin filaments anchored aperiodically within Z discs.

Mhc^{7} and *Act88F*^{KM88} have broad effects on the proteome: at least 10 additional proteins are missing or reduced in the IFM of *Mhc*^{7} (Mogami and Hotta, 1981; Chun and Falkenthal, 1988). One of these proteins, RLC, has been shown to be synthesized and degraded, suggesting that the absence of MHC triggers proteolysis of thick filament-associated proteins. Alternatively, a mechanism of regulated proteolysis may operate normally in the IFM to eliminate unassembled RLC. These results demonstrate that thick and thin filaments can assemble independently of each other but, as discussed below, the formation of native sarcomeres of regular length and width is strictly dependent on proper stoichiometry of the two filament types. The results also demonstrate that the expression (or accumulation) of subsets of contractile proteins is highly interdependent.

Many contractile protein genes are haploinsufficient for muscle development. Heterozygote loss-of-function mutants have defective myofibrillar structures (review: Bernstein *et al*., 1993). For example, *Mhc* null heterozygotes produce reduced levels of protein, have myofibrillar defects, and are flightless (Mogami *et al*., 1986). The most common defect seen in mutant heterozygotes is out-of-register peripheral myofilaments surrounding a well-ordered core of hexagonally arranged thick and thin filaments (**Figure 7**). The consistency of this phenotype, regardless of the mutant gene, suggests that assembly starts at the center and radiates out, and that actomyosin interactions are important for establishing and/or maintaining sarcomeric order during assembly (Reedy and Beall, 1993a). There are few mutants, such as *Act88F*^{G245D}, that cause myofibrillar degeneration preferentially in the center of the myofibril (Sakai *et al*., 1990; Naimi *et al*., 2001). Developmental defects also tend to be more pronounced in the IFM than in the leg or jump muscle. Certain loss-of-function mutant heterozygotes (e.g., FLN and kettin) show normal or nearly normal muscle structure in the pharate adult (Vigoreaux *et al*., 1998; Hakeda *et al*., 2000). The ultrastructural defects that are evident in the IFM of mutant *ket* and *fln* heterozygotes appear after eclosion and are likely precipitated by contractile activity.

Gene copy number can also be manipulated by transgenic approaches. Transgenic flies with excess (three or four) copies of the *Mhc* gene (with its own 5′ and 3′ flanking sequences) were shown to overexpress MHC and exhibit ultrastructural defects, namely excess thick filaments at the periphery of the myofibrils (Cripps *et al*., 1994). The presence of three or four copies of the *Mhc* gene increased MHC levels by 1.5- and 2-fold, respectively, and resulted in decreased flight performance. EM revealed concomitant defects in the IFM, with excess thick filaments at the periphery of a well-formed myofibril core. Homyk and Emerson (1988) found that increasing the *Mhc* gene copy to three using a chromosomal duplication had no effect on flight performance or wing posture (and presumably muscle structure as well). Nevertheless, the duplication does affect muscle function when placed in a genetic background deficient for TnT (Homyk and Emerson, 1988). In the case of actin, increasing the gene copy number to four does not appear to affect flight performance dramatically (Hiromi *et al*., 1986). The latter study needs to be extended, however, to establish if higher levels of actin are present in the IFM and to determine the nature of possible myofibrillar defects.

Tropomyosin is also essential for normal muscle structure. The IFM of the *TmI* hypomorph *Ifm(3)3* shows various sarcomeric defects including Z bands that are irregular in size and shape, and disordered arrays of peripheral myofilaments. Sarcomeres are also, on average, shorter than in the wild-type (2.7 μm versus 3.4 μm) (Karlik and Fyrberg, 1985; Miller *et al*., 1993). This mutant also shows defects in jump muscle ultrastructure manifested by disorganized and variably shaped myofibrils. However, it is not known if these structural anomalies reflect developmental defects or induced atrophy from muscle use, since only adult flies were examined. Kreuz *et al*. (1996) used a deficiency which deletes both *TmI* and *TmII* and found that haploidy of *TmI* causes myofibrillar disruptions in the IFM as well as flightless behavior, while haploidy of only *TmII* causes neither. As for *Ifm(3)3*, it is not known if the deficiency brings about errors in development or not (Kreuz *et al*., 1996). Another caveat of the study of Kreuz *et al*. is that protein expression levels were not measured. Thus, while reduced *TmI* expression is the most likely explanation for the observed haploid effect, it is possible that other factors (e.g., alterations in the expression or assembly of interacting proteins) could account for the defects.

Sarcomeres are not present in the IFM of *TnT* mutants that eliminate (*upheld*^{2}) or greatly reduce (*upheld*^{3}) expression of TnT in this muscle. Instead, the IFM displays loosely organized thick filament skeins and randomly scattered I–Z–I brushes (Fyrberg *et al*., 1990a). Menke and Peterson (1989) showed that early in IFM development, the overall

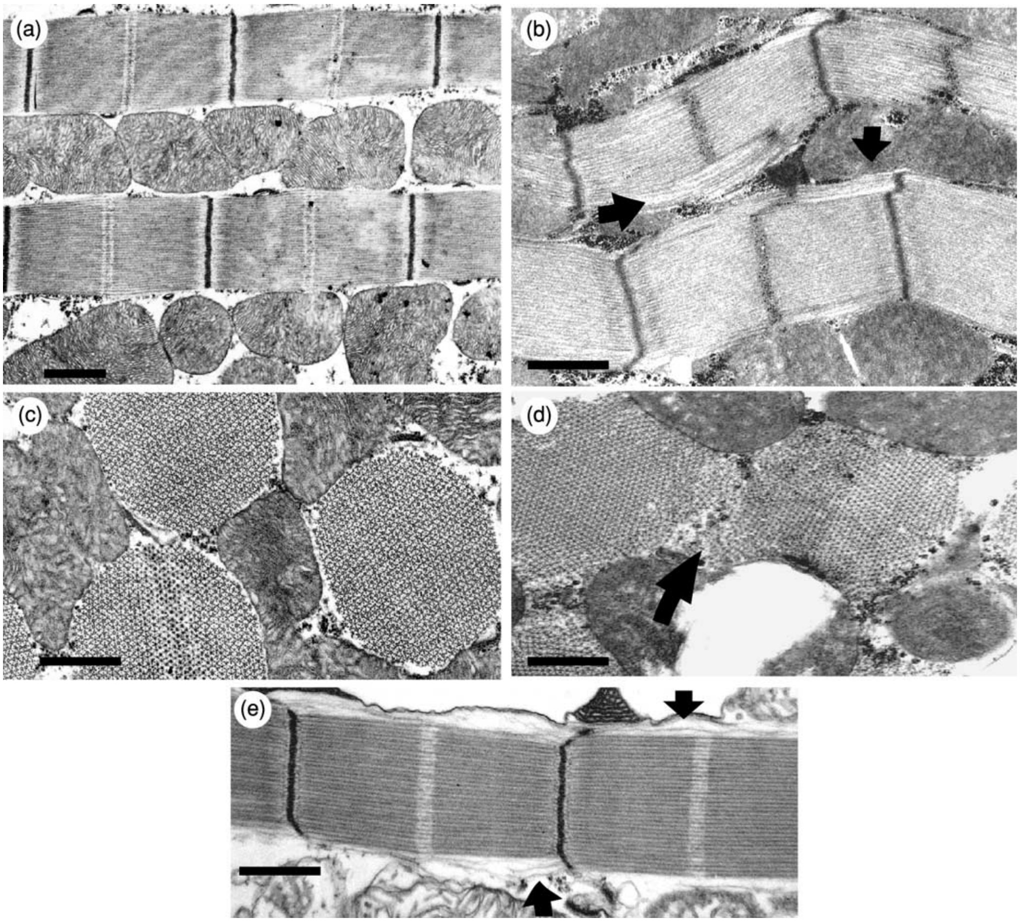

Figure 7 Myofibrillar defects in the indirect flight muscles (IFM) of the *flightin* mutant heterozygote *Df(3L)fln*[1]. Longitudinal (a, b, and e) and transverse (c, d) sections of *Df(3L)fln*[1] heterozygotes reveal disruptions in the periphery of the sarcomere (arrows) amid a well-preserved central core. Peripheral myofilaments are loosely organized resulting in sarcomere width inhomogeneities and disruptions in the double hexagonal arrays of thick and thin filaments that are evident in the myofibrillar core as well as in myofibrils from wild-type IFM (a, c). Note also that mutant myofibrils do not show the regular cylindrical shape characteristic of wild-type myofibrils. (e) Treatment of *Df(3L)fln*[1] fibers with a detergent ''skinning'' solution removes the majority of the loosely associated peripheral myofilaments. A few remaining myofilaments wander freely along the myofibrillar surface (arrows). Scale bar = 1 μm. For further details, see Vigoreaux *et al.* (1998).

pattern of protein expression in *upheld*[2] is similar to that of wild-type, but the mutant IFM begins to express two heat shock proteins at approximately 61 h APF, perhaps in response to the presence of unassembled or misfolded proteins. Similarly, mutants that fail to express one or more IFM TnI isoforms (*heldup*[3], *heldup*[4], *heldup*[5]) lack sarcomeres despite the presence of thick and thin filaments (Deak *et al.*, 1982; Beall and Fyrberg, 1991). The fact that myofibrils are absent in newly eclosed mutant adults is indicative of developmental defects and not syndromes associated with contractile activity (Beall and Fyrberg, 1991).

The IFM normally expresses very low levels of mPm. In contrast, transgenic lines in which the *mPm* gene is regulated by the *Act88F* promoter, express three to five times more mPm than wild-type flies (Arredondo *et al.*, 2001b). The higher mPm levels have little or no effect on myofibril assembly, mPm localization, thick filament diameter, or expression of other myofibrillar proteins. Nevertheless, subtle developmental defects are evident and flies display moderate flight impairments. More importantly, transgenic *Act88F–mPM* flies, which express higher levels of mPM, show more developmental defects and age-dependent degeneration of the IFM than transgenic flies in which the *mPm* gene is regulated by its own promoter (Arredondo *et al.*, 2001b). Thus, reprogramming the transcriptional activation of the *mPm* gene results in small developmental defects which are later magnified in the working muscle.

The higher levels of mPm expression cannot be explained by higher transcriptional activity of the

Act88F promoter since an *Act88F* promoter–headless myosin chimeric transgene does not result in overexpression of the rod construct over the wild-type MHC (Cripps *et al.*, 1999). Interestingly, IFM myofibrils in transgenic *Act88F* promoter-fln^{+} have narrower diameters (i.e., less thick filaments) than in the wild-type suggesting that premature activation of *fln* transcription has an effect on thick filament number (Barton *et al.*, 2002). This contrasts the situation with fln^{0} where the absence of flightin results in thick filaments that have longer than normal length (Reedy *et al.*, 2000).

Mutations in Z band-associated proteins interfere with normal myofibril assembly. Rare homozygous escapers of the weak hypomorphic *kettin* allele ket^{5} show Z bands that do not intersect the entire width of the sarcomere, resulting in peripheral myofilaments that are out of register (Hakeda *et al.*, 2000). Mutants in α-actinin that affect RNA splicing ($fliA^{3}$ and $fliA^{4}$) also show myofibrillar defects. The mutant $fliA^{3}$ expresses very low levels of α-actinin in the IFM and tubular leg muscles, mostly the slower migrating supercontractile muscle isoform (Roulier *et al.*, 1992). In newly eclosed adults, IFM sarcomeres are relatively normal except for Z bands that appear thin and punctate (Roulier *et al.*, 1992). In older adults, however, the Z disc disintegrates causing thick and thin filaments to loose their lateral registration. This is in contrast to $fliA^{4}$, in which α-actinin expression is similarly reduced, but no age-dependent degeneration is observed. One interpretation of these results is that the nature of the α-actinin isoform expressed in $fliA^{3}$, rather than a reduction in its quantity, is responsible for the muscle degeneration (Roulier *et al.*, 1992) (see Section 2.2.3.3.1.3).

In light of the studies summarized above, the muscle defects seen in contractile protein gene aneuploids can be ascribed to quantitative imbalances. While this has been demonstrated in some mutants (e.g., MHC and RLC; Warmke *et al.*, 1992; Cripps *et al.*, 1994), it is not universally true and other mechanisms must be invoked to explain defects in muscle development of IFM mutants. Nevertheless, there is strong evidence that correct stoichiometry of the major contractile proteins is important for normal IFM development (Beall *et al.*, 1989; Cripps *et al.*, 1994). Alterations in the actin : myosin protein ratio result in abnormal assembly, as evidenced by unintegrated peripheral myofilaments and occassional fraying of the hexagonal lattice, and nonfunctional muscle that leads to flight impairment. The *Act88F* null heterozygote and the *Mhc* null heterozygote display more myofibrillar defects than the *Act88F* : *Mhc* double null heterozygote. One interpretation of these results is that filament imbalances, rather than an absolute deficit of one myofilament type, is the underlying cause of the myofibrillar defects (Beall *et al.*, 1989).

In summary, more detailed developmental analyses of the above mutants are needed to establish the stage at which myofibril assembly is impaired and the molecular processes that are perturbed by each mutation. The regulatory mechanisms that coordinate contractile protein synthesis and assembly remain largely unexplored.

2.2.3.3.1.2. Effects of mutant proteins In addition to loss-of-function mutants, the study of flight muscle development has been greatly aided by mutations that result in amino acid changes in contractile proteins. Analysis of these mutants has provided insights into the sequence of developmental events that lead to the formation of the myofibril. Furthermore, the study of genetic interactions, mutations in separate genes that either suppress or enhance the mutant phenotype of a separate locus, are also providing valuable insights into the protein interactions that are fundamental for myofibril assembly (Homyk and Emerson, 1988; Prado *et al.*, 1995; Kronert *et al.*, 1999; Naimi *et al.*, 2001; Nongthomba *et al.*, 2003).

Mutations in the genes for actin and MHC are among the most frequently recovered in genetic screens that rely on a flight test to select mutants. In contrast, screens that rely on visual inspection of IFM morphology have helped uncover recessive loci that are involved in early and late stages of adult myogenesis (Nongthomba and Ramachandra, 1999). Results from these studies have been discussed in detail in several reviews (Drummond *et al.*, 1991; Bernstein *et al.*, 1993; Sheterline *et al.*, 1998; Swank *et al.*, 2000; Vigoreaux, 2001) and, for this reason the discussion is limited to the general trends rather than to an in-depth analysis of each mutant strain.

Different missense mutations in *Act88F* have been described that interfere with actin's interaction with other myofibrillar proteins. For example, the two mutants $Act88F^{E334K}$ and $Act88F^{E93K}$ form thin filaments but lack Z bands (Drummond *et al.*, 1991; Sparrow *et al.*, 1991). The absence of α-actinin and other high molecular weight proteins in the IFM of $Act88F^{E93K}$ suggests that this mutation interferes with normal assembly of the Z band (Sparrow *et al.*, 1991). This effect is probably independent of the mutation's effect on tropomyosin binding and actomyosin kinetics (Bing *et al.*, 1998; Razzaq *et al.*, 1999; review: Vigoreaux, 2001). Another actin mutant that causes defects in Z band assembly is

Act88F^{G6AA7T}, in which amino acids 6 and 7 (glycine and alanine, respectively) are converted to alanine and threonine. In this mutant, multiple level Z bands that fail to cross the entire width of the myofibril are found. As a result, unanchored peripheral thin filaments of opposite polarities are present within the same half sarcomere. This is evidenced by the formation of reverse rigor chevrons by the myosin cross-bridge (Reedy *et al*., 1989).

Another group of actin mutations (*Act88F*^{R28C}, *Act88F*^{E334Q}, and *Act88F*^{G268D}) result in abnormal fiber morphology in the developing pupa (Nongthomba *et al*., 2003). In some cases, fibers detach from the cuticle and this is followed by partial or complete hypercontraction during or after eclosion. The hypercontraction phenotype suggests a role for contractile forces in muscle development (see Section 2.2.3.3.1.4). In contrast, the mutant *Act88F*^{R95C}, which maps to the myosin S1 binding site, has no efffect on the initial myofibril development but leads to highly disrupted and hypercontracted fibers after eclosion (An and Mogami, 1996; Nongthomba *et al*., 2003).

Like *Act88F*, many *Mhc* alleles have been recovered from screens of flightless flies. Several missense mutations have been characterized that have little or no noticeable effect on muscle development but render the muscle susceptible to breakdown in the adult. An interesting example is *Mhc*^{13}, a point mutation in the light meromyosin (LMM) region of the myosin rod that changes a glutamic acid for a lysine. The structure of the developing myofibril is relatively unaffected but the mutation interferes with the normal accumulation of FLN in the IFM (Kronert *et al*., 1995). The absence of FLN leads to hypercontraction and rapid degeneration of the myofibril subsequent to eclosion. Though the mutation is in a constitutive exon that is expressed in every muscle, the phenotype is manifested primarily in the IFM suggesting that the absence of FLN, rather than an intrinsic defect in the myosin filament, compromises muscle structure. Other studies, showing that binding of FLN to myosin rod is abolished by the *Mhc*^{13} mutation (Ayer and Vigoreaux, 2003) and that *fln*^{0} manifests a phenotype similar to *Mhc*^{13} (Reedy *et al*., 2000), provide further evidence that the myosin rod–flightin interaction is essential for the establishment of structurally sound thick filaments.

Mhc^{9} is a missense mutation in the adult-specific alternative exon 9a (used in IFM and TDT) that results in a glutamic acid 482 to lysine change in a region of the myosin motor close to the actin binding site (Bernstein and Milligan, 1997). In IFM, the mutation behaves like the null allele *Mhc*^{7}, i.e., it prevents the accumulation of myosin and of the same subset of proteins that appear missing or reduced in *Mhc*^{7} (O'Donnell *et al*., 1989). Thick filaments and myofibrils are absent. Abnormal structure and reduced number of thick filaments are also seen in the four small anterior cells of the TDT. The mutation most likely affects protein stability, as evidenced by normal accumulation of *Mhc* RNA in the IFM and TDT. A similar mutation in *Caenorhabditis elegans* myosin abolishes ATPase activity, raising the possibility that abnormal interaction with actin may lead to protein instability in the developing muscle (Kronert *et al*., 1994). However, the fact that the mutant myosin fails to accumulate in IFM that lacks thin filaments, argues against this possibility and leaves open the question of how the myosin motor domain participates in myofibril assembly (Kronert *et al*., 1994; Cripps *et al*., 1999).

A caveat of many of the studies summarized above is that muscle structure was examined only in mature adults, while there is little information on muscle development *per se*. Detailed developmental analysis of each mutant strain is necessary to establish if and when each mutation interferes with myofibrillar assembly. An important distinction to be made is whether a particular mutation disrupts assembly or permits normal assembly only to give rise to a compromised myofibril with insufficient structural integrity. This is particularly true for actin and myosin mutants, where there is a broad repertoire of mutants, but very few have been examined developmentally (Drummond *et al*., 1991; Bernstein *et al*., 1993; An and Mogami, 1996; Sheterline *et al*., 1998; Swank *et al*., 2000).

2.2.3.3.1.3. Effect of isoform substitutions Unlike the case with vertebrate muscles, there is little evidence of isoform switching during development of flight or leg muscle in *Drosophila* (Caplan *et al*., 1983; Swank *et al*., 2000). As mentioned above (see Section 2.2.3.3.1), a 45 kDa TMOD isoform replaces a 43 kDa isoform well after the majority of myofibril assembly is completed (Mardahl-Dumesnil and Fowler, 2001). Maturational changes in TnT isoforms also occur in the flight muscle of dragonfly, affecting the temperature-dependent Ca^{2+} sensitivity of muscle activation. As a result, mature adult muscle is able to generate more force per unit area than newly emerged adult muscle (Fitzhugh and Marden, 1997).

There is ample evidence that distinct muscle types express different isoforms of contractile proteins, but the extent to which these differences influence developmental decisions is far less clear. One way of

approaching this question is to use transgenic techniques to express a protein isoform distinct from the one normally expressed in the muscle. In the case of actin, isoforms have been shown not to be functionally interchangeable, as demonstrated by the expression of a human (β)-cytoplasmic actin in the IFM of the actin null *Act88F*^{KM88} (Brault *et al.*, 1999). This actin, which differs from IFM actin in only 15 residues, can assemble into thin filaments to which endogenous myosin cross-bridges attach. Overall sarcomeric organization is nevertheless deficient, perhaps due to the inability of the cytoplasmic actin to interact with one or more actin-binding proteins in the IFM (Brault *et al.*, 1999). Similarly, Fyrberg *et al.* (1998) found that converting the flight muscle actin-encoding gene to one specifying a nonmuscle *Drosophila* isoform, a change entailing a total of 18 amino acid replacements, resulted in disruption of IFM structure and function. Interestingly, the majority of single isoform-specific amino acid replacements did not perturb myofibril assembly. However, when portions of the *Drosophila Act88F* actin gene were substituted with corresponding regions of genes encoding other isoforms, most constructs engendered myofibrillar defects, whose severity correlated with the number of replacements within the chimeric genes (Fyrberg *et al.*, 1998). These studies showed that, while most individual amino acid changes are tolerated, replacements of multiple amino acids are not. It is not known when or how these isoform substitutions perturb myofibrillogenesis.

In contrast to actin, *Drosophila* MHC isoforms are functionally interchangeable for development but not for physiology or, in some cases, muscle stability. Substitution of individual adult-specific alternative exons with their embryonic counterparts has no effect on IFM development (Swank *et al.*, 2001, 2003). Similarly, a mutation that results in the substitution of exon 9a for exon 9b has no effect on the assembly properties of myosin in the TDT (Kronert *et al.*, 1991). Wells *et al.* (1996) created transgenic *Drosophila* that expressed a single embryonic MHC isoform in all muscles. This isoform permitted normal development of IFM and TDT, indicating that the type of MHC isoform expressed in a muscle does not dictate the structural qualities of the sarcomere. However, transformed flies are flightless and show reduced jumping ability. In addition, the IFM myofibrillar structure deteriorates in aging adults, but not in the TDT. The aging effect on IFM ultrastructure is partly ameliorated by substituting the C-terminus of the embryonic MHC transgene with the adult C-terminus, suggesting that this region of the molecule is important for stability of IFM myofibrils (Wells *et al.*, 1996; Swank *et al.*, 2000).

Tropomyosin isoforms are also functionally interchangeable. In *Drosophila*, two isoforms that differ at their C-termini are encoded by the *TmI* gene: Ifm-TmI is expressed in IFM and TDT, while Scm-TmI is expressed in other muscles of the larva and adult (Miller *et al.*, 1993). Miller *et al.* (1993) demonstrated that the IFM and TDT tolerate isoform substitutions by using a transgene encoding the Scm-TmI to correct the *Ifm(3)3*-induced defects in both muscle types (see Section 2.2.3.3.1.1).

2.2.3.3.1.4. Role of mechanical forces The development of vertebrate striated muscle has been shown to be influenced by mechanical forces (Simpson *et al.*, 1994). Flow-induced forces imparted by the circulating blood are also essential for vertebrate heart development (Taber, 1998). There is some evidence, albeit indirect, that externally applied and internally generated forces are important epigenetic factors in flight muscle development. For example, the DLM of the cricket *T. oceanicus* contracts during the nymphal instars in the absence of neural activity and before it becomes functional for flight (Ready and Josephson, 1982).

Longitudinal growth of the flight and jump muscles of the blowfly *Calliphora vomitoria* occurs in response to stretch at the time of emergence from the puparium. Houlihan and Breckenridge (1981) proposed that the expansion of the newly eclosed blowfly from air intake and increased hemolymph pressure brings about lengthening of the sarcomere. Changes in sarcomere length are also associated with increased actomyosin ATPase activity (Houlihan and Breckenridge, 1981). The number of sarcomeres along a myofibril remains constant, in contrast to pupal development, where muscle growth is believed to occur through increased number of sarcomeres by Z band splitting (Houlihan and Newton, 1979) (but see Section 2.2.3.1). The increased sarcomere length must be accompanied by elongation of thick and thin filaments, but this has not been shown conclusively. Cutting of the tendon guide cells appears to halt sarcomere elongation and induces muscle shortening, consistent with the idea that muscle grows in response to tensile forces (Houlihan and Newton, 1979). Force transmission at the muscle–tendon junction may also explain why certain α-actinin mutations in *Drosophila* result in more disruption of terminal Z bands than of internal sarcomeric Z bands (Fyrberg *et al.*, 1990b). The molecular mechanisms by which muscle senses and responds to mechanical stress are not understood.

Studies of *Drosophila* IFM mutants are providing increasing evidence that contractile forces play a determining role in myofibril assembly. In the mutant *heldup*^{2}, a single amino acid substitution in TnI (alanine 116 for valine) causes hypercontraction of the IFM that begins to manifest approximately 78 h APF (Naimi *et al.*, 2001). The muscle condition progressively worsens resulting in complete loss of sarcomere structure just 2 days after eclosion (Beall and Fyrberg, 1991). The assembly defects engendered by *heldup*^{2} are likely to result from unregulated contractions, as evidenced by the following observations. The condition is ameliorated in *heldup*^{2};*Mhc*^{7} double mutants, in which thick filaments are absent (Beall and Fyrberg, 1991). A screen for genetic suppressors of the wings up phenotype of *heldup*^{2} uncovered an intragenic mutation, a mutation in TM, and four mutations in the MHC motor domain (Prado *et al.*, 1995; Kronert *et al.*, 1999; Naimi *et al.*, 2001). The mechanism(s) by which the second site mutations suppress muscle hypercontraction has not been established, but the results of these studies implicate unregulated, Ca^{2+}-activated actomyosin-generated tension as the underlying cause of the *heldup*^{2} developmental defect. More recently, Nongthomba *et al.* (2003) isolated additional *Mhc* missense alleles that act as suppressors of *heldup*^{2} and *upheld*^{101}, a TnT point mutation that shows similar characteristics to *heldup*^{2} (Fyrberg *et al.*, 1990a). The finding that the IFM hypercontraction phenotype of *heldup*^{2} and *upheld*^{101} can also be suppressed by the transgenic "headless" myosin (lacking the motor domain) provides further evidence that contractile forces are generated during myofibril assembly (Nongthomba *et al.*, 2003). How these forces impact muscle development remains to be established.

Mutations in the regulatory subunit of the *Drosophila* protein phosphatase calcineurin (*canB2*) also result in a hypercontracted phenotype, in which the bulk of the IFM fiber mass collapses towards the posterior end of the thorax (Gajewski *et al.*, 2003). The mutation preferentially affects the DLM, with little or no effect on the DVM or the jump muscle. Like *heldup*^{2}, developing IFM fibers in *canB2* mutant pupae begin to shorten irreversibly during day 3 of pupal development. Calcineurin is known to function in cell signaling pathways in a variety of cell types, including vertebrate cardiac and skeletal muscle, but its role in IFM development has not been elucidated.

2.2.3.3.2. Formation of the myotendon junction Epidermal cells that will contribute to the formation of the myotendon junction (MTJ) in *Drosophila* IFM are defined as early as the third larval instar by expression of the transcription factor Stripe (Fernandes *et al.*, 1996). These cells form four clusters located in the notal region of the disc epithelium in close association with myoblasts (**Figure 4**). The target genes for Stripe have not been identified but genes that encode structural proteins are likely candidates (Roy and VijayRaghavan, 1999). Mutants in the *stripe* gene preferentially affect the DLM, while mutants in the *vertical wing* gene affect DVM, DLM, and TDT in decreasing order of severity (Deak, 1977b; de la Pompa *et al.*, 1989). The function of *vertical wing* is not known but fate mapping experiments suggest its primary site of action is not the muscle (Deak, 1977b). The product of *erect wing* (*ewg*) is a transcription factor that is expressed in imaginal progenitor myoblasts (DeSimone *et al.*, 1996).

The attachment sites for both ends of the DLM and the dorsal ends of the DVM and TDT arise from the wing imaginal disc, while the attachment sites for the ventral ends of the DVM and the TDT arise from the leg imaginal disc. Another difference between the two flight muscles is that imaginal myoblasts that fuse to form DVM do not express integrin (PS-2α), while those that fuse with larval remnants to form DLM do express this protein (Fernandes *et al.*, 1996). The expression of PS-2α is likely to be regulated by D-Mef2 and mutants of the latter show abnormal pattening and reduced size DLM (Ranganayakulu *et al.*, 1995).

Once the muscle contacts the epidermis, different integrins are detected at the muscle and epidermal ends (**Table 2**). PS-2α first appears in myoblasts that surround the persistent larval templates during metamorphosis, but the expression ceases after a few hours (Fernandes *et al.*, 1996). It then reappears after the initial steps in muscle development are completed (i.e., approximately 24 h APF), a timing that is more consistent with a role in the stabilization and maturation of the muscle–epidermal contacts (Fernandes *et al.*, 1996). Mutations in the *struthio* gene, which encodes a putative RNA binding protein, cause flight impairments that most likely arise from defects in epidermal muscle attachment sites (Lo and Frasch, 1997). Moreover, TDT development is curtailed by a mutation (*mys*^{nj42}) in the PS-β integrin gene, suggesting that a different integrin is involved in the formation of the MTJ for this muscle (Wilcox *et al.*, 1989).

The ends of developing IFM fibers project filopodium-like extensions that reach towards epidermal cells that express PS-1α (Roy and VijayRaghavan, 1999). The first processes that connect muscle cells to the epidermis are epidermal in origin, at least for

the anterior ends of DLM (Fernandes *et al.*, 1996). Using ultrathin section electron microscopy, Reedy and Beall (1993b) provided a detailed description of the ultrastructural events that result in formation of the flight muscle MTJ. Extensions of tendon guide cells first contact developing myotubes shortly before myofibrils begin to asssemble. Focal dense plaques at the membrane junctions thicken and enlarge to form a modified terminal Z band that links the myofibril to the membrane via a dense feltwork. Abundant microtubules play a prominent role on both sides of the junction. Muscle microtubules form transient "sleeves" surrounding developing myofibrils, while tendon cell microtubules merge with specific dense sites on the junctional membrane and later link the tendon cell basal membrane to its apical (cuticular) membrane (Reedy and Beall, 1993b). Mutations in *α-actinin* disrupt myofibrillar attachments at the terminal Z band (Fyrberg *et al.*, 1990b). Mutations in *kettin* also have been shown to disrupt this structure. In $ket^{14}/+$ mutant heterozygotes, the terminal Z band is reduced in size, and some myofilaments appear to bypass this structure and contact the cell membrane directly (Hakeda *et al.*, 2000).

Differentiation of the DVM MTJ is under the control of BRC-Z1, a zinc finger transcription factor encoded by the *Broad Complex* (*BRC*) ecdysone responsive gene (Sandstrom and Restifo, 1999). *BRC* mutants of the *reduced bristles on palps* (*rbp*) complementation group, which encode BRC-Z1, have few intact DVM fibers that are often attached to incorrect locations on the epidermis (Sandstrom *et al.*, 1997). The mutations also affect the attachment of the DLM and TDT demonstrating that rbp^+ function is required for the formation and maintenance of the MTJ. Using mosaic flies whose thoracic muscles and epidermis were of different genotypes, Sandstrom and Restifo (1999) demonstrated that BRC-Z1 acts in the dorsal epidermis, not in the muscle fiber, to establish the correct location and formation of the MTJ.

The attachment sites for the DFM are formed by *stripe*-expressing epidermal cells in the wing hinge primordium. Unlike the IFM, additional *stripe*-independent mechanisms that rely on *D-Wnt-2* are involved in the formation of muscle attachment sites (Kozopas and Nusse, 2002). Regions of *D-Wnt-2* expression in the wing hinge primordia are adjacent to regions of *stripe* expression; however, mutants in *D-Wnt-2* that affect patterning of DFM do not interfere with *stripe* expression.

2.2.3.3.3. Functional specialization of muscle types Ultrastructural and biochemical changes of the flight muscle accompany the transition to adulthood and the subsequent maturational progression. Among the most dramatic changes are in the activity of metabolic enzymes and on the size, ultrastructure, and number of mitochondria (Scaraffia *et al.*, 1997). Changes in flight muscle size and ultrastructure during adult maturation are well documented for a variety of insect taxa (review: Marden, 2000). For example, the cross-sectional area of the mitochondria increases during adult maturation in dragonfly, in response to aerodynamic demands and ecological challenges. For the desert locust *S. gregaria*, mitochondrial growth during flight muscle development occurs independently of JH or ecdysteroid hormone titers (Wang *et al.*, 1993). In contrast, flight muscle hypertrophy is under juvenile and ecdysteroid hormone control, but neural factors also play a role in some species (Marden, 2000). JH also influences flight muscle degeneration in insects that no longer have a need to fly (e.g., in crickets initiating reproductive activity after migratory flight).

Differences among muscle types are clearly reflected in the structure and composition of the myofibril. Some generalities in sarcomere design are well known, e.g., asynchronous IFM have a lower thin-to-thick filament ratio than synchronous flight muscle (3 : 1 versus 5 : 1 or higher) (Squire, 1986; Josephson *et al.*, 2000). A major strategy for achieving functional specialization is differential expression of contractile protein isoforms that impart fiber-specific physiological properties. For example, maximum velocity of muscle shortening (V_{max}) in the vertebrate muscle is in large part determined by the particular myosin isoform expressed in that tissue (Lowey *et al.*, 1993). Thus, it comes as no surprise that *Drosophila* IFM myosin has among the fastest *in vitro* motility velocity ever recorded for a striated muscle myosin (Swank *et al.*, 2001). Surprisingly, there is no correlation between unloaded shortening velocity (V_{max}) and wing beat frequency among the various insects tested (Marden, 2000).

The muscle may also modulate the relative expression of proteins to achieve distinct biomechanical properties. The amount of Pm varies over a broad range among insect muscle types, and differences in Pm content are often associated with thick filaments that differ in form and size (Beinbrech *et al.*, 1985; Maroto *et al.*, 1996). Differences in metabolic enzyme activity also have been documented during flight muscle development (Deak, 1977a) and among populations (Zera *et al.*, 1985). In the latter case, expression of polymorphic loci encoding metabolic enzymes is thought to directly influence flight performance (e.g., flight duration

and aerodynamic power output) (Barnes and Laurie-Ahlberg, 1986).

A second strategy for achieving functional specialization is the recruitment of protein isoforms to perform distinct roles. For example, two different molecular weight variants of projectin are expressed in the IFM and tubular muscles of *Drosophila* (Vigoreaux *et al.*, 1991). These two isoforms, which are likely generated by alternative splicing, also differ in their sarcomeric distribution; I band in the IFM and A band in tubular muscles (Vigoreaux *et al.*, 1991; Daley *et al.*, 1998). These differences in protein structure and sarcomere distribution suggest that IFM and tubular projectins perform different functions. However, this has yet to be demonstrated. Another example is *Drosophila* mPm, which is found all through the A band in the TDT but restricted to the M line and the ends of thick filaments in IFM. It is unclear what, if any, are the functional consequences of this difference in distribution. Unlike *Drosophila*, *Lethocerus* mPm is distributed along the entire length of the thick filament in both IFM and TDT (Maroto *et al.*, 1996). In addition, the distribution of the flight muscle specific isoform of glycerol-3-phosphate dehydrogenase (GPDH-1) is restricted to the sarcomere M line and Z band. A different GPDH isoform (GPDH-3) that differs by the absence of a C-terminal tripeptide, does not show the sarcomeric distribution of GPDH-1 when expressed transgenically in the IFM of a *Gpdh* null mutant (Wojtas *et al.*, 1997). Furthermore, transgenic expression of GPDH-3 also affects the localization of two additional glycolytic enzymes. These results indicate that the IFM isoform of GPDH may have the added role of organizing glycolytic complexes in the myofibril.

A third strategy is the expression of novel proteins that are restricted to specific muscle types. Examples include the flight muscle-specific proteins FLN (Vigoreaux *et al.*, 1993), TnH (Bullard *et al.*, 1988), arthrin (Bullard *et al.*, 1985), and zeelin 2 (Ferguson *et al.*, 1994). Arthrin is found only in asynchronous IFM of most Diptera and Hemiptera but is not found in the IFM of Hymenoptera or Coleoptera (Peckham *et al.*, 1992). TnH is found in both synchronous and asynchronous flight muscle (Peckham *et al.*, 1992). The species distribution of zeelin 2 and FLN has not been examined. A distinct form of TnC is predominant in the IFM (Qiu *et al.*, 2003). The Z band protein Z(210) also shows a limited muscle distribution, found only in the large cells of the TDT and in the IFM (Vigoreaux *et al.*, 1991). The expression of MRP in tubular muscles (some DFM and leg muscles) but not in IFM very likely contributes to the distinct sarcomere assemblies and function of these two muscle types. MRP is randomly integrated along the thick filament, resulting in irregular patches of smooth and cross-bridge bearing thick filaments, and disordered thick and thin filament arrays (Standiford *et al.*, 1997). Another thick filament protein, MP20, is expressed in tubular muscles but not IFM (Ayme-Southgate *et al.*, 1989). The availability of mutants for some of these proteins should help to elucidate their roles in the developmental histories and functional properties of fibrillar and tubular muscles.

The two classes of insect flight muscle, synchronous and asynchronous, differ in many physiological properties including their frequency of contraction, mechanical power output, and efficiency of energy utilization (Josephson *et al.*, 2001). While many factors contribute to these differences, one of the primary determinants is the amount of space allocated to each of the three major structural units of the muscle cell: mitochondria, myofibrils, and membrane systems. In the asynchronous IFM, large rows of mitochondria lie alongside abundant myofibrils, while the sarcoplasmic reticulum is very scarce. The synchronous flight muscle has a much higher proportion of sarcoplasmic reticulum, myofibrils of smaller diameter, and fewer mitochondria (Josephson and Young, 1987; Josephson *et al.*, 2000). In the migratory locust *Locusta migratoria* mitochondria enlarge up to 30-fold during maturation of the flight muscle (Sogl *et al.*, 2000). The jump muscle, on the other hand, has few mitochondria (5% of muscle volume) but an extensive sarcoplasmic reticulum (20% of muscle volume) (Schouest *et al.*, 1986). Flight muscle is also characterized by abundant interfibrillar tracheoles. Studies on *Locusta* and other species have shown that tracheolization precedes genesis of mitochondria and coincides with the peak of lactate dehydrogenase activity (Beenakkers *et al.*, 1985). Anaerobic metabolism ceases once interfibrillar tracheoles are fully developed, and adult specific metabolic patterns take over.

It remains to be established how space allocation decisions are made during muscle development. Understanding the genetic control of these processes represents a significant challenge given the importance of cellular allocation in dictating the eventual functional capacity of the muscle.

2.2.4. Summary

The mechanism by which contractile proteins assemble into a sarcomeric lattice remains ill defined. Substantial headway has been made into understanding particulars but great challenges remain.

Cell culture and *in vitro* approaches have been instrumental in understanding myofibrillogenesis of vertebrate skeletal and cardiac muscle but their usefulness for insect systems has been limited. Instead, the combination of genetics and cell imaging techniques has proven instrumental for the understanding the sequence of events *in vivo*. In this respect, *D. melanogaster* has been and will continue to be a valuable model system for the study of myofibrillogenesis.

2.3 Functional Development of the Neuromusculature

D E Featherstone, University of Illinois at Chicago, Chicago, IL, USA
K S Broadie, Vanderbilt University, Nashville, TN, USA

2.3.1. Introduction and Overview

The neuromusculature drives movement. It is composed of three functionally intertwined cell types: (1) beautifully patterned striated body muscles; (2) architecturally elaborate motor neurons that precisely innervate these muscles; and (3) peripheral glia that maintain and modulate motor neuron transmission. For the last century or more, numerous insect species have been exploited to study the basis of neuromuscular development and function. The primary attractions of insect systems include large individually identifiable neurons, simple neuromuscular architecture, and easy propagation and manipulation of insect species in the laboratory. A well-refined maps of insect neural circuits and detailed physiological insight into the bases of insect neuromuscular development and function are provided. Until approximately 20 years ago, most

insect physiologists focused on species such as grasshoppers, crickets, cockroaches, or moths, which have particularly large, experimentally tractable cells. In the last two decades, increasingly, the vast majority of studies in insect physiology and neuromuscular development have shifted to the tiny fruit fly, *Drosophila melanogaster*. The reason, of course, is that *Drosophila* has emerged as a premier genetic model system. This amenability to genetic manipulation, coupled with the increasing molecular focus of physiology and development, has led to the fruit fly's dominance as the insect model for studies in development, physiology, and behavior, despite the considerable disadvantage of small size compared to larger insect species. Although other insect species still dominate fields including ecology, toxicology, and endocrinology, modern insect development and physiology is, for the most part, now synonymous with *Drosophila* development and physiology. Thus, an accurate review of advances in insect neuromuscular development focuses on *Drosophila*, and this chapter will focus strongly on details of the *Drosophila* neuromusculature.

The neuromusculature has been most intensively investigated in mammals, but, in general, neuromuscular function and development is very similar in insects and mammals. There are, however, some important differences. The most obvious difference is that in insects, muscle contraction is triggered by the excitatory neurotransmitter glutamate. The vertebrate neuromuscular junction (NMJ) uses acetylcholine. However, glutamate is the primary excitatory synapse type in the vertebrate central nervous system (CNS). Thus, in addition to being a general model of the insect NMJ, the *Drosophila* NMJ has also served as a leading genetic model of glutamatergic synapses. *Drosophila* studies have concentrated on glutamatergic "type I" NMJ synapses on embryonic and larval muscles, which drive muscle contraction. There has been much less focus on "type II" or "type III" synapses, which serve primarily modulatory functions. Therefore, unless specified otherwise, this chapter will discuss *Drosophila* type I NMJ synapses. The focus of this chapter is on the acquisition and maturation of physiological properties (e.g., functional development) of these NMJs in the embryo and larva. This chapter does not discuss the development that occurs in pupae during metamorphosis (see **Chapters 2.2 2.4**, and **2.5**).

This chapter begins with an overview of the components and function of the mature larval *Drosophila* neuromuscular system (see Section 2.3.1). The cell types of the neuromusculature, the physiological properties of these cells, and patterns of neuromuscular connectivity are discussed (see Sections 2.3.1.1 and 2.3.1.2), and then summarize the functional properties of NMJ transmission (see Sections 2.3.1.3 and 2.3.1.4). The bulk of the chapter is then devoted to the functional development of this neuromuscular system. First, the origin and morphological development of the *Drosophila* neuromusculature is given, describing the specification of cellular identities and the maturation of neuromuscular patterning and connectivity (see Sections 2.3.2–2.3.4). This information is not intended to be exhaustive, but rather to provide references for the reader to accurately place functional maturation within the wider context of overall neuromuscular development. More comprehensive descriptions of neuromuscular structural and functional development can be obtained in **Chapters 1.10** (neurogenesis), **2.1**, and **2.2** (myogenesis), **2.4**, and **2.5**. Second, the functional development of the NMJ synapse is focused. The maturation of neurotransmitter release (see Section 2.3.5), induction of postsynaptic specializations and the appearance of postsynaptic receptor fields (see Sections 2.3.6–2.3.7), the interaction between pre- and postsynaptic cells (see Section 2.3.7), developmental changes in functional plasticity (see Section 2.3.8), and the effects of hormones on NMJ function (see Section 2.3.9) are discussed. The chapter is concluded by considering the most pressing unanswered questions and suggesting fruitful directions for investigation in the future.

2.3.1.1. Types of Cells

2.3.1.1.1. Motor neurons Compared to vertebrates, insects have a relatively simple neuromusculature composed of relatively a few cells (see **Figures 1 and 2**). Rather than a motor neuron pool (hundreds of cells) innervating a multicellular muscle (thousands of myotubes), as in mammals, insects are characterized by a single motor neuron innervating a single myotube. Moreover, as they are bilaterally symmetrical segmented animals, the basic unit of the insect neuromusculature is a single hemisegment, which is simply reiterated a number of times depending on the length of the animal. Each hemisegment is nearly identical, with a few segment specific modifications overlying a common cellular plan. Thus, in the *Drosophila* embryo/larva body, thoracic segments T1–T3 are highly similar (although each is unique) and the abdominal segments A2–A7 are identical (A1 and A8 have slight variations). Insect neurobiologists work with identified, named neurons. In most insect species, neurons are readily discernible via basic imaging techniques, and can be individually identified in living preparations based

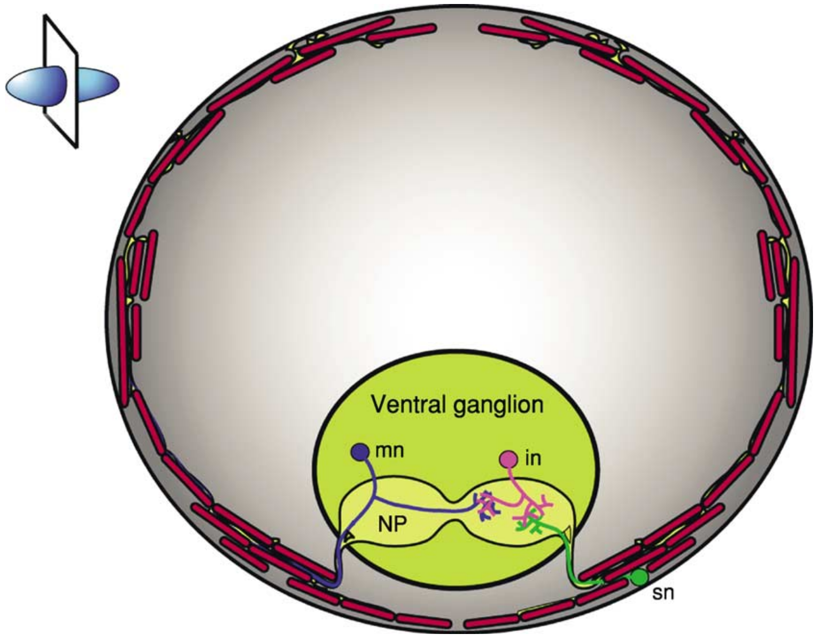

Figure 1 Diagrammatic representation of the *Drosophila* embryonic/larval neuromusculature, viewed in cross-section. One of each general type of neuron is shown: motor neuron (mn), interneuron (in), and sensory neuron (sn). The cell bodies of motor neurons and interneurons lie within the cortex of the ventral ganglion. The cell bodies of peripheral sensory cells are found near the cuticle in the periphery. Motor neurons send axons either contralaterally or (as shown) ipsilaterally along the ventral nerve and into the peripheral musculature, where the axons (yellow) synapse onto one (or sometimes more, depending on the neuron) appropriate muscle target(s) (red rectangles). Note that the most distal muscle targets are also most dorsal, since axons grow along the periphery from the ventral side of the animal. Simultaneously, sensory neurons project their axons from the periphery back toward the CNS along ventral nerves. Although the motor and sensory axons are shown traversing different nerves in this diagram for clarity, each nerve actually contains multiple motor axons going out and multiple sensory axons going in. Interneurons lie entirely within the ventral ganglion. Neuron–neuron synapses occur within the neuropil (NP), the area of the ventral ganglion containing most axonal and dendritic tracts, but no cell bodies.

on cell body size, location, and axonal projection. For example, drosophilists commonly visualize a single raw prawn 3 (RP3) motor neuron innervating a specific pair of ventral, longitudinal muscle cells (muscles 6 and 7; Broadie *et al*., 1993). The application of cell-filling techniques and antibodies further increases the number of identified, named neurons. Due to their large size, clear axonal projections, and known function, motor neurons have received the most focused analysis and are best characterized. In the large grasshopper embryo, all identifiable motor neurons have been described. Motor neuron cell identities have been highly conserved among diverse insect species, allowing studies from different insect species to cross-fertilize and inform parallel studies in other species (Thomas *et al*., 1984). Knowledge gleaned from the grasshopper, in particular, provided the vital framework for subsequent studies in *Drosophila*.

In the *Drosophila* embryo/larva, all motor neurons in the identical A2–A7 abdominal segments have been named and mapped. A combination of transgenic markers and antibodies also assign unique molecular identities to many of these cells. Motor neurons share two general organizational properties. First, the neuronal structure is simple, with either a unipolar structure or a weakly bipolar structure. Typically, motor neuron axonal projections are either ipsilateral or contralateral, with a limited dendritic tree branching from a single process near the soma. Second, motor neurons innervating muscles of similar position (dorsal versus ventral) and orientation are often clustered, with overlapping dendritic trees that converge in the same region of the neuropil. Even in cases where neurons innervating similar muscles have soma positions that are quite different, the cells share a common domain of dendritic arborization within the CNS (Landgraf *et al*., 1997). Each hemisegment has 30 muscles and each muscle is (with a few exceptions) innervated in a 1 : 1 arrangement by one of 30 “major” motor neurons. These motor neurons display distinctive, enlarged “type I” NMJ boutons that drive muscle contraction. In addition to these 30 major motor neurons, there are four motor neurons that each innervate a large field of muscles and have characteristically smaller NMJ boutons. These

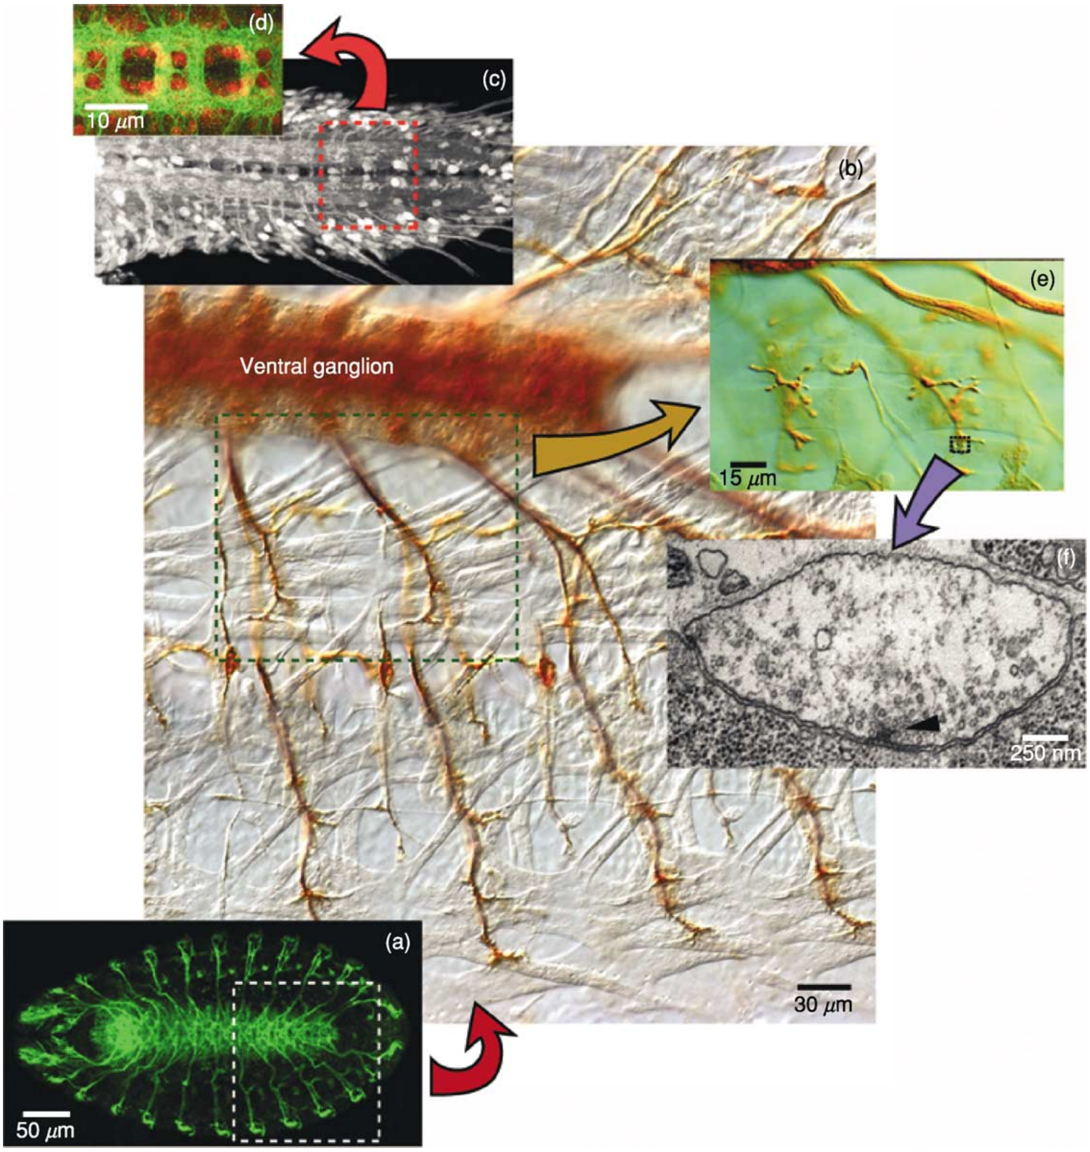

Figure 2 Microscopic views of the *Drosophila* embryonic neuromuscular anatomy. (a) Confocal image of an intact (whole mount) embryo viewed from above (anterior is left). Anti-FasII antibodies have been used to visualize the motor nerves (green). Note the segmentally repeated peripheral nerves extending from the ventral ganglion out toward the body wall neuromusculature. (b) An enlarged view of a section of the embryonic peripheral neuromusculature. As in (a), axons and growth cones (brown) have been visualized using antibodies that recognize the cell adhesion molecule FasII. In each hemisegment, a group of axons extends from the ventral ganglion, where they first encounter the ventral longitudinal muscles (two hemisegments of which are enclosed by the dashed green box). Some axons continue on toward more distal, dorsal muscles (the dorsal midline is near the bottom of the image). The embryo in (b) has been split dorsally and laid flat; in the intact animal, the axons extending toward the bottom of the image (and the muscles they innervate) would curve up out of the page and back toward the ventral ganglion, such that the bottom of the image (which shows the dorsal midline) would overlap the midline of the ventral ganglion. (c) A close-up of the ventral ganglion, showing a subset of neurons visualized using green fluorescent protein (GFP) expressed specifically in cholinergic neurons (GAL4-Cha;UAS-GFP). Note the two parallel areas devoid of cell bodies; these are the neuropile. (d) A more detailed image of approximately 2.5 neuromeres of ventral ganglion, showing axons (green) and cell bodies (red). The overall appearance of a ''ladder'' is formed by segmentally repeated lateral and commissural axon tracts. (e) A detailed view of a portion of two neighboring hemisegments showing NMJs (brown) on ventral longitudinal muscles 7 and 6. The edge of the ventral ganglion is visible in the upper left corner. (f) An electron micrograph cross-section of a stage 17 embryonic neuromuscular bouton. The arrow indicates a presynaptic T-bar, surrounded by synaptic vesicles.

motor neurons are believed to mediate modulatory functions. Thus, in total, there are 34 identified motor neurons per abdominal hemisegment.

Until recently, relatively little was known about the functional properties of *Drosophila* motor neurons *in situ*. Recent physiological assays have focused on a small, medial dorsal cluster of motor neurons with both ipsi- and contralateral axons terminating in type I glutamatergic muscle terminals (Hoang and Chiba, 2001; Rohrbough and Broadie, 2002). These cells have resting potentials of −50 to −60 mV and fire repetitive action potentials (AP) during a depolarizing current injection (Rohrbough and Broadie, 2002), consistent with the sharp bursts of action potentials that drive peristaltic movement *in vivo* (Broadie and Bate, 1993e; Cattaert and Birman, 2001). The majority of motor neurons exhibit adaptive AP firing patterns, characterized by a variable decrease, but not termination, in spike frequency that is likely specific to each cell type (Rohrbough *et al*., 2003). A few motor neurons exhibit tonic firing at constant frequency during prolonged depolarization. Similar adaptive and tonic AP firing characteristics have been previously described in cultured *Drosophila* neurons (Saito and Wu, 1991; O'Dowd, 1995; Zhao and Wu, 1997; Schmidt *et al*., 2000). *In situ*, the heterogeneity of AP firing properties among specific motor neurons is likely regulated by intrinsic variables such as different patterns of impinging synaptic input.

A considerable amount is known about the voltage-gated ion channels that mediate electrical signaling in *Drosophila* motor neurons (Wu and Ganetzky, 1992; see also **Chapters 2.6** and **5.1**). The primary voltage-gated Na^+ channel is encoded by the *paralytic* (*para*) gene, although at least one other voltage-gated Na^+ channel is also present (Loughney *et al*., 1989). The other primary inward current is carried by Ca^{2+} via several distinct classes of voltage-gated Ca^{2+} channels. The gene *cacophony* (*cac*) encodes the L-type voltage-gated Ca^{2+} channel in *Drosophila* (Kulkarni and Hall, 1987). Null mutations in the *Dmca1A* gene result in embryonic lethality; partial loss-of-function mutations reduce the L-type Ca^{2+} current (Smith *et al*., 1996). Presynaptic N-type Ca^{2+} channels regulate neurotransmitter release (Rieckhof *et al*., 2003).

The hyperpolarizing outward K^+ current can be divided into at least four components: two voltage-gated K^+ currents (I_A, I_K) and two calcium-gated K^+ currents (I_{CF}, I_{CS}). The *Shaker* (*Sh*; encodes I_A channel) and *ether-a-gogo* (*eag*; encodes a subunit of multiple K^+ channels) genes were identified based on hyperactivity of mutants under anesthesia (Ganetzky and Wu, 1983; Ganetzky *et al*., 1999). Double *eag;Sh* mutants show a highly elevated frequency of action potentials in motor neurons and heightened neurotransmission at the NMJ. In cell body recordings, the principal I_A current is not carried by *Sh* channels but rather by channels encoded by the *Shaker cognate l* (*Shal*) gene, which exhibits different kinetics (Tsunoda and Salkoff, 1995a). Null *Shaker* mutants do not display altered I_A currents in records from embryonic motor neuron cell bodies (Rohrbough *et al*., 2003). Thus, it has been suggested that *Shal* encoded I_A dominates in neuronal cell bodies and/or axons, whereas *Shaker* encoded I_A dominates in synaptic terminals (Tsunoda and Salkoff, 1995b). The neuronal I_K current is carried by at least two channels; the larger component mediated by a slowly inactivating channel encoded by *Shaker cognate b* (*Shab*) and the smaller component mediated by a noninactivating channel encoded by *Shaker cognate w* (*Shaw*) (Solc and Aldrich, 1988; Tsunoda and Salkoff, 1995a). The I_{CF} current is encoded by the *slowpoke* (*slo*) locus and *slo* mutants completely lack the Ca^{2+} activated K^+ current (Elkins *et al*., 1986; Elkins and Ganetzky, 1990). The channel or channels carrying the I_{CS} current have not yet been identified (Chopra *et al*., 2000).

Acetylcholine (ACh) and GABA are the primary excitatory and inhibitory neurotransmitters, respectively, in the insect CNS (see **Chapters 5.4** and **5.9**). This conclusion is based primarily on neurotransmitter and receptor expression studies, electrophysiology, and (in *Drosophila*) transgenic reporters specific to transmitters – green fluorescent protein coupled to, for example, choline acetyltransferase expression (Schuster *et al*., 1993; Jonas *et al*., 1994; Aronstein *et al*., 1996; Yasuyama and Salvaterra, 1999). Glutamatergic cells and glutamate receptors (both NMDA and non-NMDA types; see also Section 2.3.1.3) are also expressed throughout the CNS (Littleton and Ganetzky, 2000), but less is known about their circuit function. Larval motor neurons *in situ* respond to iontophoretic application of ACh, GABA, and glutamate (Rohrbough and Broadie, 2002). As expected, ACh is strongly excitatory, generating sustained depolarizations and usually driving bursts of action potentials. ACh responses are mediated by nicotinic ACh receptors as evidenced by their reversible blockade by d-tubocurare (dtC; Rohrbough and Broadie, 2002). GABA and glutamate cause inhibitory responses mediated primarily by Cl^- channel currents. Glutamate-gated currents are particularly prolonged and act to strongly suppress AP firing. Both inhibitory transmitters display similar reversal potentials near normal resting potential (∼−55 mV), and

are reversibly blocked by the Cl^- channel blocker picrotoxin (Rohrbough and Broadie, 2002). Thus, motor neurons *in situ* express functional receptors appropriate for excitatory cholinergic input and inhibitory GABAergic and glutamatergic input.

Motor neurons display several distinct types of endogenous synaptic activity, ranging from fast, unitary events to sustained excitatory currents and potentials. Both endogenous and evoked events require external Ca^{2+} and are reversibly blocked by dtC application, demonstrating cholinergic synaptic input. These cells display unitary spontaneous excitatory synaptic currents (sepscs; 5–50 pA) closely resembling fast cholinergic sepscs reported in *Drosophila* cultured neurons (Lee and O'Dowd, 1999; Lee and O'Dowd, 2000; Lee *et al*., 2003). Most striking, however, are endogenous events with much larger amplitudes and longer durations termed spontaneous rhythmic currents (SRCs) or potentials (SRPs) that appear to be a type of periodic endogenous excitatory motor output, supporting bursts of AP firing (Rohrbough and Broadie, 2002). Interestingly, blockade of NMDA-type glutamate receptors abolishes centrally generated endogenous rhythmic output at the NMJ (Cattaert and Birman, 2001). Thus, while cholinergic input provides the major excitatory synaptic drive to motor neurons, additional forms of central transmission, including glutamatergic input, likely shape the frequency and pattern of motor rhythms controlling coordinated movement.

Compared to our knowledge of motor neurons residing in the comparatively simple and invariant central abdominal segments, relatively little is known about the physiology, identity, or connectivity of cells upstream of the motor neurons (Lohr *et al*., 2002; Landgraf *et al*., 2003; Taghert and Veenstra, 2003). There are an estimated 200 neurons per hemisegment neuromere. Apart from the few identified neurosecretory cells (Taghert and Veenstra, 2003), which also send projections into the periphery, the vast bulk of these cells are interneurons, both local and projection subtypes. Almost all of these interneurons remain unnamed and their functions remain uncharacterized. Interneurons functionally upstream of motor neurons have cell bodies scattered throughout the central and lateral CNS neuropil and numerous varicosities (presumed synaptic boutons) overlapping spatially with the dendritic arbors of motor neurons (Rohrbough *et al*., 2000; Rohrbough and Broadie, 2002). Paired synaptic recording and cell labeling experiments indicate that fast synaptic responses in motor neurons are efficiently evoked when stimulation is applied to the neuropil adjacent to the motor neuron's primary dendrites (Rohrbough and Broadie, 2002; Rohrbough *et al*., 2003), suggesting that cholinergic inputs are formed by ascending or descending longitudinal axons.

2.3.1.1.2. Peripheral glia As in other animals, glia are an abundant cell type in the insect CNS and peripheral nervous system (PNS). Just how abundant, is a matter of debate, as estimates range widely and little effort has been made to catalog glial subtypes. In the *Drosophila* CNS, glial cells adopt morphologies resembling vertebrate astrocytes, yet essentially nothing is known about their mature functions. In the periphery, defined glial cells are found where peripheral nerves exit the CNS, and at regular intervals along the peripheral nerves (Auld *et al*., 1995; Sepp *et al*., 2000). These glia associate tightly with both motor and sensory axons, and have extensive cytoplasmic processes that fully ensheath peripheral nerves. The number of insulating peripheral glial cells per nerve seems to be somewhat variable (8–10 per hemisegment in *Drosophila*) and the exact cell body positions are not well mapped. Therefore, there is no general nomenclature or numbering scheme for *Drosophila* peripheral glia, unlike the situation for both motor neurons and muscles. In addition to *bona fide* peripheral glia, there are other cell types closely associated with the peripheral nerves. For example, *Drosophila* also contains nerve associated cells that are characterized by persistent larval expression of the transcription factor Twist. These persistent Twist (PT) cells represent the mesodermal anlage of the adult muscle that divide during larval life to form the adult myoblasts (Bate *et al*., 1991; Broadie and Bate, 1991).

In many animals, peripheral glia have been shown to be essential for action potential conduction, and thus neuromuscular transmission. Similarly, *Drosophila* peripheral glia tightly wrap around all exposed peripheral nerves, enclosing afferent and efferent axons in a common glial sheath that excludes the hemolymph (Auld *et al*., 1995). Adjacent glial processes are joined by a specialized intercellular junction called a pleated septate junction (pSJ), which acts as a diffusion barrier similar to the tight junctions of vertebrates (Schulte *et al*., 2003). Although less highly specialized than the myelin sheath of mammalian Schwann cells, this insect glial sheath seems to serve comparable functions. Mutation of any of three *Drosophila* genes encoding glial proteins (Gliatactin, Neurexin IV, and Axotactin) causes blockade of motor nerve action potential propagation and, therefore, paralysis (Auld *et al*., 1995; Baumgartner *et al*., 1996;

Yuan and Ganetzky, 1999). The *gliatactin* and *neurexin* IV mutants manifest very subtle disruptions in the glial sheath surrounding the motor nerves, and the conduction blockade can be rescued by reducing [K^+] in the external bath, indicating that the glial sheath is essential for insulating the peripheral nerves from the high [K^+] of the insect hemolymph. In contrast, Axotactin appears to be part of a novel glia–neuron signaling pathway required for proper electrical signaling in neuronal axons (Yuan and Ganetzky, 1999). The functional roles of the glia in neuronal signaling remain to be elucidated. Nuclei of glial sheath cells lie on the outside of the motor nerve just proximal to the site where nerves enter the body wall musculature. This nerve entry point on the muscle is the location where the glial sheath covering the motor nerve terminates; insect NMJs are not covered in any sort of "capping" glia, unlike vertebrate NMJs.

2.3.1.1.3. Muscle *Drosophila* muscle is similar to mammalian muscle: syncytial (multinucleate; arising from myoblast fusion) and beautifully striated with actin–myosin contractile units (sarcomeres). However, the insect muscle can be very different at the level of multicellular organization. For example, in the *Drosophila* embryo/larva, a given muscle is composed of a single syncytial cell, whereas in mammals, each muscle is composed of a large aggregate of syncytial muscle cells (myotubes). In the adult *Drosophila* thorax, however, bundles of muscle cells do become the basic contractile unit, paralleling the situation in mammals (see also **Chapter 2.2**). The insect muscle attaches directly to the epidermis via specialized tendon cells distributed so that individual muscles span longitudinal, transverse, or oblique domains. Each segment has a highly specific, invariant pattern of muscles, each of a certain size and orientation, typically arranged in a number of discrete layers (Bate, 1990; **Chapter 2.2**). Muscle cells vary greatly in size, depending on the number of myoblasts that fuse to give rise to the mature myotube. In the *Drosophila* embryo/larva, each abdominal hemisegment A2–A7 contains exactly 30 muscles, arranged in three comparably sized layers (~10 muscles/layer; Bate, 1990; **Chapter 2.2**). Each *Drosophila* muscle has a distinguishing name, although two different naming schemes are routinely used (Bate, 1993).

In *Drosophila*, larval muscles are geometrically simple (typically rectangular) and nearly isoelectric throughout; their passive electrical properties have been well characterized (Jan and Jan, 1976b; Wu and Ganetzky, 1992; Singh and Wu, 1999). Muscles are weakly electrically coupled within and between segments (Ueda and Kidokoro, 1996). In contrast to vertebrate muscle, insect muscle lacks voltage-gated Na^+ channels, and Ca^{2+} influx is required for insect muscle contraction (Aidley, 1975; Jan and Jan, 1976b; Singh and Wu, 1999). In total, five prominent voltage-activated currents are present in mature larval muscle; the voltage-gated calcium current (I_{Ca}), two voltage-gated potassium currents (I_A, I_K), and two calcium-gated potassium currents (I_{CF}, I_{CS}) (Wu and Ganetzky, 1992; Singh and Wu, 1999).

The voltage-gated Ca^{2+} channels are present in two subtypes: one with the pharmacological and biophysical properties of vertebrate L-type Ca^{2+} channels (high voltage activation; maximal at −10 to 0 mV threshold, inactivate slowly) and the other with the characteristics of the vertebrate T-type Ca^{2+} channels (low voltage activation threshold) (Gielow *et al.*, 1995). In *Drosophila*, two Ca^{2+} channel α subunit genes, *Dmca1A* and *Dmca1D*, encode channels with six transmembrane domains, both similar to the vertebrate voltage-gated Ca^{2+} channels (Zheng *et al.*, 1995; Smith *et al.*, 1996). Definitive genetic analyses of the function of these gene products in muscle has not yet been done.

Of the two voltage-gated K^+ currents, I_A is rapidly activated and rapidly inactivated, whereas I_K is slowly activated and shows little inactivation during sustained depolarization. I_A is selectively eliminated in *Sh* mutants; the *Drosophila Sh* gene was the first cloned K^+ channel α subunit, a six transmembrane voltage-gated channel (Kamb *et al.*, 1987; Kamb *et al.*, 1988). Thus, the molecular identity of the principal I_A is different in neurons and muscle; Shaker I_A is only detectable in a subpopulation of neurons, and even in these neurons does not constitute the major I_A current (Baker and Salkoff, 1990; Tsunoda and Salkoff, 1995a). In contrast, the *shaw* and *shab* genes encoding I_K channels in neurons are also responsible for the I_K current present in muscle (Tsunoda and Salkoff, 1995a). Mutations in the *Shab* gene reduce I_K without affecting I_A.

Of the two Ca^{2+}-activated K^+ currents, I_{CF} is rapidly activated downstream of Ca^{2+} channel opening and inactivates, whereas I_{CS} activates slowly and shows little inactivation. Mutations of the *slowpoke* (*slo*) gene eliminates I_{CF} in muscle (Elkins *et al.*, 1986; Wu and Ganetzky, 1992). The channel carrying I_{CS} has not yet been identified (Chopra *et al.*, 2000). Additional genes for K^+ channel subunits have been identified in *Drosophila* muscle, including *eag*, a structural K^+ channel subunit, and *Hyperkinetic* (*Hk*), an auxiliary, membrane associated β subunit (Yao and Wu, 1999). Mutations in *eag* alter all four K^+ currents in the muscle, reducing all but eliminating none, and it has been

suggested that *eag* acts as a modulatory subunit in several different K^+ channels (Zhong and Wu, 1993). In contrast, mutations in *Hk* alter the kinetics of the I_A current alone, without affecting any of the others (Yao and Wu, 1999; Wang *et al.*, 2000).

In addition to these voltage- and calcium-gated channels, a mechanically gated, stretch-activated large conductance K^+ channel is present in *Drosophila* muscle (Zagotta *et al.*, 1988; Gorczyca and Wu, 1991). The molecular identity and exact functional significance of these channels remains unknown.

Synaptic transmission at the NMJ is mediated by ionotropic glutamate receptors (GluRs), which are L-glutamate gated cation channels expressed in all muscles (see **Chapter 5.9**). Electrophysiological evidence for other receptors exists (see later sections), but the molecular identity of these proteins remains unknown. The exact subunit composition of any *Drosophila* channel, either ligand or voltage-gated, and the functional consequences of channel modulation also remain largely unknown.

2.3.1.2. Overview of Neuromuscular Connectivity

2.3.1.2.1. Patterns of motor innervation Many insects contain segmental ganglia. In *Drosophila*, however, segmental ganglia are fused into one ventral nerve cord (VNC), although segmental units (neuromeres) can be recognized by landmarks including segmental nerves. Each neuromere consists of a nearly identical set of cortical neuronal somata in characteristic positions, enclosing a soma-free zone (neuropil) dense with synaptic connections. The neuropil is scaffolded by a highly recognizable "ladder" of two lateral axon tracts (longitudinal connectives) connected across the midline by an anterior and posterior axon tract (transverse commissures). Synaptic contacts within the CNS are restricted to the neuropil excluding the neuronal soma. Most motor axons converge at lateral exits located on the side of each hemisegment neuromere. Two major axon tracts converge on these exits: (1) the anterior intersegmental nerve (ISN) tract and (2) the posterior segmental nerve (SN) tract. A small number of axons also exit the CNS through a dorsal exit point in each segment (see **Figures 1 and 2**).

In the periphery, five major nerves extend from each lateral CNS exit point. First, the ISN carries the motor innervation to the most dorsal muscle set. Second, multiple SN branches innervate the lateral and ventral muscles: the A branch (SNa) innervates the lateral muscle group, the B branch (SNb) innervates the next most lateral/ventral muscle group, the C branch (SNc) innervates the internal ventral muscles, and the D branch (SNd) innervates the most ventral, external muscle group. From the dorsal CNS exit extends the transverse nerve (TN) that runs along the anterior segmental border. The TN carries just a few motor axons together with the processes of neurosecretory cells (Taghert and Veenstra, 2003).

2.3.1.2.2. Morphological and functional classes of NMJ In *Drosophila*, motor neurons innervating larval muscle have been classified as types I, II, and III (see **Chapters 2.1** and **2.2**). Most motor neurons (~32/hemisegment) are type I. Type I neurons use glutamate as their primary neurotransmitter and are the principal mediators of muscle excitability and contraction. Type I terminals are usually restricted to one muscle, contain thick, variably branched arbors, and typically extend terminal branches for only a relatively short distance from the entry point. Type I NMJ varicosities, or boutons (**Figure 2f**), are deeply embedded in the muscle membrane, and are characterized presynaptically by dense pools of small, clear synaptic vesicles (SVs) clustered around T-bars marking glutamate release sites (active zones) and postsynaptically by an extensive field of elaborate muscle membrane foldings called the subsynaptic reticulum (SSR). The SSR is an expanded area of postsynaptic receptivity that contains the GluRs and dense concentrations of other proteins involved in postsynaptic glutamatergic transmission. Morphologically, type I neurons come in two subdivisions: (1) type Ib neurons possess big (2–5 μm) boutons that innervate muscles on a 1 : 1 basis and (2) type Is neurons possess small (1–3 μm) boutons that innervate several adjacent muscles. Type Is NMJ boutons have a greatly reduced SSR relative to type Ib. These two neurons drive physiologically different patterns of transmission, varying in excitation threshold, excitatory junctional current (EJC) amplitude, and functional plasticity properties (Kurdyak *et al.*, 1994). It has been proposed that type Ib and Is NMJ terminals are analogous to the well-characterized crustacean tonic and phasic NMJs, respectively.

There are only two type II motor neurons per hemisegment, which innervate a large number of adjacent muscles in the dorsal and ventral muscle fields. Compared to type I boutons, type II NMJ terminals are characterized by much longer, much thinner, branched arborizations studded with small (<1 μm) synaptic boutons. Type II terminals are glutamatergic and contain small, clear SVs, but they predominantly contain larger, elliptical dense core vesicles (DCV) holding a variety of neuromodulators (e.g., biogenic amine (octopamine) and small peptide (proctolin) transmitters; Taghert and

Veenstra, 2003). Type II terminals do not appear to activate ionotropic receptors in the muscle, but likely work through G protein-coupled receptors, most of which have not been characterized. Hence, type II motor neurons are proposed to be modulatory regulators of NMJ synaptic and/or muscle function, although their exact roles are not at all well understood.

Type III neuron terminals are similar to type II terminals, but contain larger DCVs harboring a different array of modulators (e.g., Insulin; Taghert and Veenstra, 2003). Type III neurons, like type II, are believed to mediate modulatory functions in the neuromusculature. At an ultrastructural level, the release sites of type III boutons are distinctive, and it is possible that these terminals are largely neurohemal, releasing peptide hormones to the entire body musculature. Types II and III NMJ terminals reside in shallow grooves in the muscle surface and are not associated with a postsynaptic SSR.

Each identified muscle cell is innervated by a specific combination of types I, II, and III motor neurons. All muscles possess type Ib innervation, in a 1 : 1 relation, but different muscles are variably innervated by type Is and type II neurons. Type III innervation is usually restricted to the centrally located muscle 12. Each motor neuron contacts each muscle at a highly characteristic nerve entry point. The NMJ structure of each muscle is highly conserved from segment to segment and from animal to animal, so much so that any given NMJ is instantly recognizable to anyone familiar with the *Drosophila* neuromuscular anatomy. However, the terminals are not invariant and may differ in the number/length of the branches and the number of synaptic boutons. Indeed, the NMJ shows a high degree of structural plasticity that is sensitive to the relative mobility and density of the animals during postembryonic development (Sigrist *et al*., 2003). Type II terminals are particularly liable to structural modification as a consequence of environmental conditions.

Several chemical classes of NMJ neurotransmission exist in different insect species. NMJs are commonly glutamatergic and excitatory, but some insects also have direct inhibitory inputs on the muscle mediated by GABA or glutamate (see also **Chapters 5.4** and **5.9**). *Drosophila* embryos and larvae have only excitatory glutamatergic NMJs with no inhibitory GABAergic or glutamatergic receptors (Featherstone *et al*., 2000). In addition to these classic, fast neurotransmitters, there are a number of other neuromodulators capable of mediating both ionotropic and metabotropic muscle responses (Taghert and Veenstra, 2003). These include neuropeptides such as pituitary adenyl cyclase activating polypeptide (PACAP)-like peptide, which (probably indirectly) gates and modulates ionic currents (Zhong, 1996) and biogenic amines, such as octopamine and tyramine (Nishikawa and Kidokoro, 1999; Nagaya *et al*., 2002), which modulate the efficacy of synaptic transmission (presumably via G protein-coupled receptors). The number of these other transmitters, potentially quite large, and the scope of their physiological functions, remains largely unknown.

2.3.1.3. Overview of NMJ Neurotransmission

The presynaptic mechanisms of neurotransmitter release have been particularly highly conserved between invertebrate and vertebrate species. In *Drosophila*, presynaptic depolarizations are typically triggered by short bursts (10–20 Hz) of action potentials, resulting in Ca^{2+} influx through N-type voltage-gated Ca^{2+} channels. Uniform, electron-lucent 30–40 nm SVs containing glutamate virtually fill the synaptic bouton, but can be functionally differentiated into three discrete pools including: (1) a reserve pool in the bouton interior removed from active cycling except under conditions of high demand; (2) a cycling pool clustered near release sites; and (3) a readily releasable pool (RRP) of vesicles morphologically docked at release sites, available for imminent release (Rodesch and Broadie, 2000). The SV release sites contain a distinctive electron-dense T-bar. In *Drosophila* and other dipterans, T-bars appear in cross-section as a bar-like density approximately 100–200 nm wide, oriented parallel to the cell membrane and supported by a “stem” approximately 50 nm in height projecting into the cytosol (Lane, 1985; Jia *et al*., 1993; Prokop, 1999). The true shape of a T-bar, however, is apparently more similar to a “table” when considered in three dimensions: three or four electron-dense “legs” or “prongs” (Rheuben *et al*., 1999) support each bar; the density typically appears as a “T” because only one “leg” is typically visible in cross-section (Atwood *et al*., 1993). The appearance of the presynaptic density varies among insect species, suggesting that its function is not dependent on a particular shape. In *Manduca*, for example, the presynaptic density appears simply as a narrow 2 nm bar. In longitudinal sections, T-bars can extend for hundreds of nm (Lane, 1985).

The T-bar is surrounded by clear SVs that are typically 30–40 nm in *Drosophila*. Because the T-bar/presynaptic density is presumably the site of synaptic vesicle fusion (or near it), each T-bar traditionally identifies an “active zone.” However, the exact role of the T-bar (or presynaptic density in

any organism) in synaptic vesicle cycling is not known. Omega-shaped membrane profiles indicative of exo/endocytosis are not always adjacent to T-bars (Lane, 1985). Omegas that are present occur some distance away and are coated, suggesting that they are endocytic. Verstreken *et al*. (2002) argued that basal release requires only partial (kiss and run) SV fusion and showed electron micrographs where the few existing vesicles that are interacting with the membrane are not clustered around T-bars. Haghigi *et al*. (2003) showed micrographs containing apparently functional active zones with clustered vesicles, but no T-bars. If vesicles mark sites of neurotransmitter release, then T-bar components are clearly not prerequisites for neurotransmitter release. The molecular composition of the T-bar is also unknown. In *Drosophila*, no molecules are yet known to be restricted to the active zone, and no mutants have been identified that eliminate the T-bar structure.

Many proteins involved in SV trafficking, fusion, and endocytosis have been exhaustively assayed in *Drosophila*. Examples include: (1) synaptotagmin, the proposed Ca^{2+} sensor for exocytosis (Littleton *et al*., 1993b; Broadie *et al*., 1994; DiAntonio and Schwarz, 1994); (2) multiple components of the soluble NSF attachment protein receptor (SNARE) complex, proposed to mediate SV fusion (Broadie *et al*., 1995; Schulze *et al*., 1995; Fergestad *et al*., 2001); (3) regulators of the SNARE complex such as Uncoordinated 13 (Unc-13) and Ras opposite (Rop)/Unc-18 (Harrison *et al*., 1994; Schulze *et al*., 1994; Aravamudan *et al*., 1999; Aravamudan and Broadie, 2003); (4) regulators of Clathrin-mediated endocytosis such as α-Adaptin and Endophilin (Gonzalez-Gaitan and Jackle, 1997; Fergestad *et al*., 1999; Fergestad and Broadie, 2001; Verstreken *et al*., 2002); and (5) mediators of SV endocytosis and recycling such as the GTPase Shibire/Dynamin (Koenig and Ikeda, 1989; van der Bliek and Meyerowitz, 1991). To a very high degree, the molecular machinery of neurotransmitter release and SV cycling is highly conserved between *Drosophila* and other species, including mammals. Many reviewers have considered the conserved nature of this machinery of neurotransmitter release in detail (Keshishian *et al*., 1996; Lloyd *et al*., 2000; Broadie and Richmond, 2002).

Postsynaptic composition and function varies according to the nature of the neurotransmitter. In *Drosophila*, muscle contraction is generated by a burst of EJCs (5–10 Hz) at the glutamatergic NMJ. Current influx through glutamate receptors is primarily carried by Na^{+} and, to a lesser extent, Ca^{2+} (Jan and Jan, 1976a). The highly folded SSR is believed to greatly increase the density of voltage-gated Ca^{2+} channels near the NMJ. Insect muscles do not contain voltage-gated Na^{+} channels. Since the presynaptic arbor can cover a considerable length of muscle area, it is likely that the synaptic response is widespread in order to mediate near-synchronous muscle contraction. In *Drosophila*, Ca^{2+} based muscle action potentials can be recorded, but it is not generally thought that larval muscles depend on regenerative potentials *in vivo* (Broadie and Bate, 1993d). In larger insects, there is clear evidence of muscle action potentials.

The nature of the postsynaptic glutamate receptor field at the *Drosophila* NMJ has been most thoroughly investigated. There are at least three functional classes of GluRs in *Drosophila* muscle including: (1) extrasynaptic ionotropic receptors; (2) synaptic ionotropic receptors; and (3) metabotropic receptors (Chang *et al*., 1994; Nishikawa and Kidokoro, 1995; Chang and Kidokoro, 1996; Parmentier *et al*., 1996; Ciani *et al*., 1997; Petersen *et al*., 1997; Zhang *et al*., 1999).

Ionotropic GluRs are multimeric L-glutamate-gated cation pores that are each composed of four subunits (Madden, 2002). Three different subunits are known to be expressed in embryonic/larval NMJs: GluRIIA, GluRIIB, and GluRIII (Petersen *et al*., 1997; DiAntonio, personal communication). GluRIII is a required subunit, and GluRIIA and GluRIIB appear to compete for assembly with GluRIII. Thus, native receptors in *Drosophila* appear to be multimers of GluRIIA/GluRIII, or GluRIIB/GluRIII (DiAntonio, personal communication).

The A and B subunits appear to have arisen through a fairly recent genetic duplication event, since the genes are adjacent in the genome, show a high level of sequence identity, and the genetic removal of either shows that neither alone is required for NMJ function and viability (Petersen *et al*., 1997). Removal of either GluRIIA or GluRIIB alters single channel current amplitude, however, suggesting that the A and B subunits confer different biophysical properties (Petersen *et al*., 1997). If both A and B subunits are eliminated, the mutant is embryonic lethal and apparently lacks all NMJ transmission. Thus, the presence of either GluRIIA or GluRIIB, but not both, along with GluRIII, is essential for function.

Mammalian GluRs were originally classified pharmacologically, based on relative sensitivity to the agonists amino-3-hydroxy-*S*-methylisoxazole-4-propionate (AMPA), kainate, and *N*-methyl-D-aspartate (NMDA). GluRIIA, IIB, and III amino acid

sequences demonstrate that *Drosophila* NMJ GluRs have highest sequence similarity to mammalian kainate receptors. Insect muscle glutamate receptors, however, are activated by quisqualate (Usherwood, 1994), as are mammalian AMPA receptors. Furthermore, heterologously expressed GluRIIA receptors are relatively insensitive to both AMPA and kainate (Schuster *et al.*, 1991). Thus, the ionotropic glutamate receptors at insect NMJs can safely be considered "non-NMDA type," but further distinctions based on mammalian receptor pharmacology are probably meaningless.

The only metabotropic glutamate receptor identified so far at the fly NMJ is encoded by the *DmGluRA* gene, which is expressed both in the CNS neuropil and at the NMJ (Parmentier *et al.*, 1996; Mohrmann and Broadie, unpublished data). Null mutants in the *DmGluRA* gene are viable, and the receptor appears to play rather subtle functions in the regulation of NMJ structure and functional plasticity (Parmentier *et al.*, 1996; Mohrmann and Broadie, unpublished data).

Other than the actual GluRs, only a few other components of the postsynaptic density are known. These proteins are, almost exclusively, present on both sides of the synaptic cleft and include: (1) transmembrane receptors such as members of the position specific (PS) integrin family (3α and 1β subunit; Beumer *et al.*, 1999, 2002) and homophilic neural cell adhesion molecules (NCAMs) Fasciclins (II and III) (Schuster *et al.*, 1996a; Davis *et al.*, 1997; Zito *et al.*, 1997); (2) membrane associated PDZ-domain anchoring proteins such as Discs Large (Dlg, a PSD-95 homolog) and the associated Scribbler protein (Budnik *et al.*, 1996; Roche *et al.*, 2002); and (3) signaling complex molecules such as Ca^{2+}/Calmodulin-dependent kinase II (CamKII), Rho-type guanine nucleotide exchange factor, and protease activated kinase (PAK) (Griffith, 1997; Beumer *et al.*, 2002; Roche *et al.*, 2002; Kazama *et al.*, 2003). Based on much longer lists compiled for other species, the majority of the components of the postsynaptic density in insects have yet to be elucidated.

2.3.1.4. Modulation of NMJ Neurotransmission

The *Drosophila* NMJ is plastic in both its structural and functional properties. The degree of electrical activity modulates the terminal size and architectural complexity of the NMJ. Hyperactivity through mutation of the K^+ channel genes *eag* and *Sh* results in a striking increase in synaptic size and complexity (Budnik *et al.*, 1990). This morphological change is causally linked to a change in the expression of the homophilic NCAM Fasciclin II (Davis *et al.*, 1996a). In addition, however, many other signaling molecules mutate to alter the degree of structural complexity including CamKII, Integrins, and many other proteins (Zhong and Shanley, 1995; Budnik, 1996; Griffith, 1997; Rohrbough *et al.*, 1999, 2000, 2003). It is likely that only a subset of these proteins are mechanistically linked to activity-dependent plasticity, whereas others simply mediate synaptic growth.

To date, only short-term (up to minutes) functional plasticity has been revealed at the *Drosophila* NMJ. It may be that longer forms of functional plasticity are not present at the insect NMJ, although practical limitations in recording configurations have simply prevented the undertaking of long-term assays. In addition, plastic features are only apparent at low $[Ca^{2+}]$, which may not reflect the normal physiological condition (Broadie, 2000). A likely explanation for this restriction is that in higher $[Ca^{2+}]$, synaptic depression caused by depletion of resources (e.g., SVs) tends to dominate over any manifestation of facilitation (Broadie *et al.*, 1997; Broadie, 2000).

Four forms of synaptic modulation are routinely assayed at the *Drosophila* NMJ. In order of duration, these are: (1) paired-pulse facilitation (PPF); (2) short-term facilitation (STF); (3) augmentation; and (4) post-tetanic potentiation (PTP). All four forms of plasticity result in elevated EJC sizes following specific patterns of stimulation. PPF is manifest on the millisecond time scale, when one stimulation is followed after a short interval by a second stimulation. Significant PPF begins at a ~100 ms interval and increases rapidly at shorter intervals. STF occurs during short, high frequency stimulation trains on the second time scale. Significant Ca^{2+} dependent facilitation usually begins with ~2 Hz stimulation trains, and increases rapidly at higher frequencies. Augmentation is a similar form of maintained facilitation that occurs during prolonged, high frequency stimulation trains. Augmentation increases with the frequency of the stimulus train and will persist for the period of stimulus. The longest term modulation, PTP, follows a prolonged, high-frequency stimulus train (5–10 Hz for >30 s) but persists after a return to a basal frequency (0.5 Hz) of stimulation. PTP represents a prolonged, low-level (25–50%) potentiation that lasts for the duration of the recording (>20 min). PTP at the *Drosophila* NMJ occurs via cAMP dependent signaling (Zhong and Wu, 1991, 1993; Renden and Broadie, 2003).

2.3.2. Development of Motor Neuron Function

2.3.2.1. Motor Neuron Morphogenesis

2.3.2.1.1. Early neurogenesis In insects, neurons are produced by progenitor cells called neuroblasts that arise from a specialized neurogenic region called the ventral neuroectoderm (for relevant reviews, see also **Chapters 1.10–1.12**). Neuroblasts are stem cells that divide repeatedly to form a specific, limited lineage of progeny. In *Drosophila*, the neuroectoderm first becomes distinguishable soon after gastrulation during the very early stages of germ-band extension (see Figure 3). Following gastrulation, a regularly spaced array of neuroblasts develop in the ventral domain of each embryonic hemisegment, interspersed among cells forming the ventral epidermis (epidermoblasts). These two sets of progenitors segregate based on a competitive interaction called lateral inhibition. The genes mediating this inhibition mechanism are called neurogenic genes, since they allow all progenitor cells to acquire a neural fate. The lateral inhibition hypothesis proposes that all cells within the

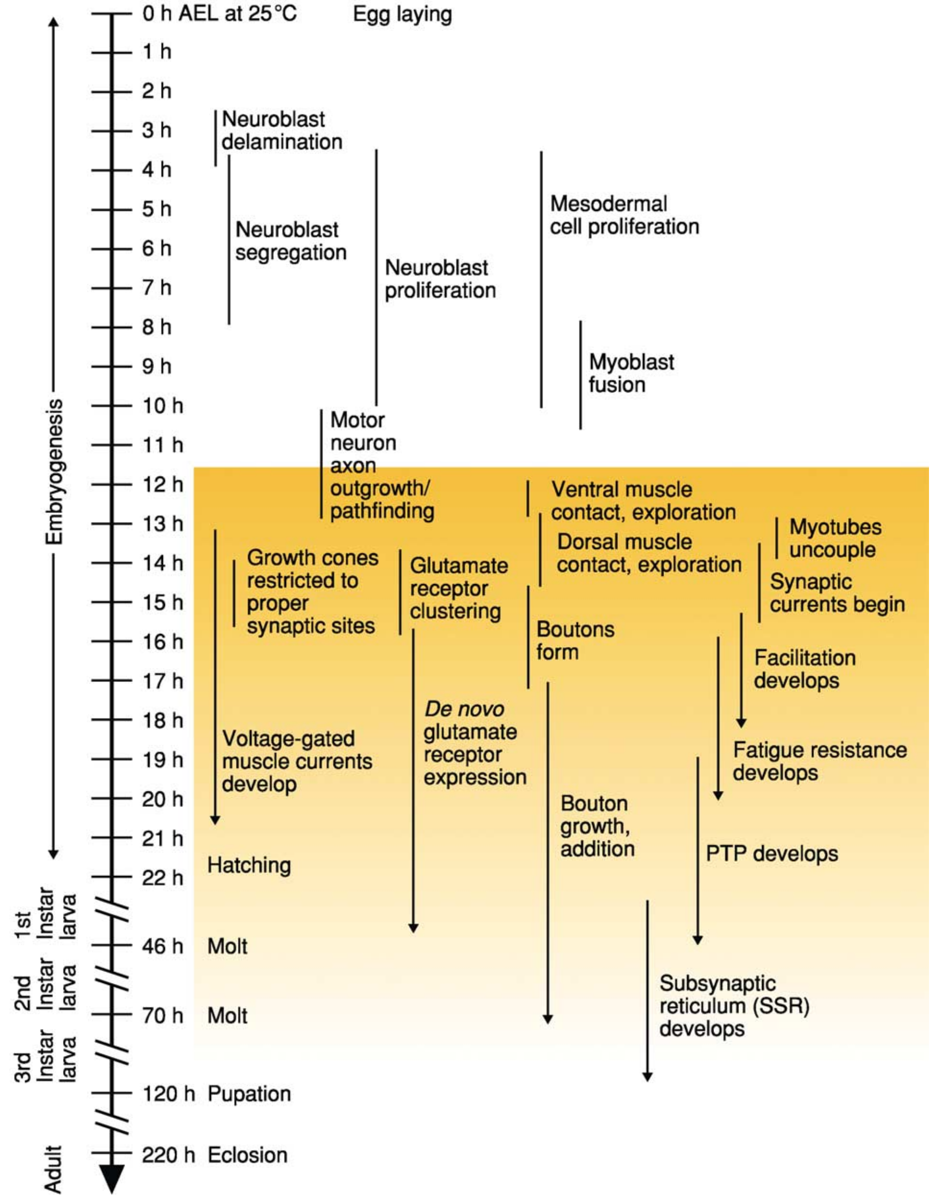

Figure 3 A timeline of *Drosophila* NMJ development. The time scale on the left represents hours after egg laying (AEL) at 25 °C. Under these conditions, embryogenesis takes approximately 22 h. Embryonic/larval NMJ synaptogenesis occurs during the period delimited by the golden color.

neuroectoderm acquire the competence to develop as neuronal progenitors (a competence group), but within each group stochastic interactions single out only a single cell to develop as a specific neuroblast. This neuroblast subsequently inhibits all the surrounding cells within the group, forcing them to assume a secondary epidermal fate. The selected neuroblasts segregate individually into the interior of the embryos ("delaminate") prior to initiating rounds of stem cell division.

In *Drosophila*, neuroblasts delaminate in three distinct phases, eventually forming a monolayer of neural stem cells between the ectoderm and the underlying mesoderm (30 neuroblasts/hemisegment). The surprisingly regular neuroblast array has allowed the production of spatial maps with individually defined, named neuroblasts, increasingly accurately defined based on the expression of specific molecular markers (Bossing *et al*., 1996; Schmid *et al*., 1999). A well-defined coordinate system of positional information (anterior–posterior, dorsal–ventral) controls the identity of neuroblasts. In *Drosophila*, each individual neuroblast can be specifically identified based on the combination of genes it expresses and, later, the characteristic lineage it gives rise to. Soon after leaving the ectodermal layer, neuroblasts become more spherical and begin to divide in a series of asymmetric divisions to generate ganglion mother cells (GMCs), which then divide symmetrically to produce two neurons. Most neuroblasts perform multiple rounds of division, with most mitotic activity ending at a period corresponding to the completion of germ-band retraction, although rare divisions may continue in late embryonic stages. In *Drosophila*, these same neuroblasts reappear, after a period of quiescence, in early postembryonic stages, to again begin producing neurons that will form the adult nervous system (Prokop and Technau, 1991).

2.3.2.1.2. Establishing motor neuron identity Cell ablation studies indicate that neuroblasts are initially quite labile in terms of fate. Elimination of a neuroblast can be compensated for by the reversal of an epidermal fate decision and the emergence of a new neuroblast. In *Drosophila* and grasshopper embryos, neuroblast ablation and transplantation experiments, together with genetic studies, have shown that GMC birth order is the primary determinant of identity (Doe and Goodman, 1985; Furst and Mahowald, 1985; Prokop and Technau, 1994; Schmid *et al*., 1999). Neuroblasts grown in single-cell isolated cultures produce defined neuronal lineages (Huff *et al*., 1989; Schmidt *et al*., 2000), suggesting that neuronal identity is largely derived from intrinsic determinants. Single identified neuroblasts grown in culture give rise to progeny that express molecular markers and functional properties expected for that lineage (Luer and Technau, 1992; Schmidt *et al*., 2000), suggesting that at least some aspects of neuronal differentiation are cell autonomous. The identity of neurons arising from early neuroblast divisions is controlled, at least largely, by intrinsic fate determinants that are asymmetrically distributed to the daughter cells. A hierarchy of transcription factors, which first function during segmentation, later regulate temporal identity in the nervous system, including *hunchback* (*hb*), *castor* (*cas*), and *Kruppel* (*Kr*) (Gaul *et al*., 1987; Cui and Doe, 1992; Mellerick *et al*., 1992; Isshiki *et al*., 2001). These transcription factors are sequentially expressed in neuroblasts, with GMCs maintaining the expression profile present at birth. This transcription factor expression specifies temporal identity and thus defines neuronal cell fate (Isshiki *et al*., 2001). Although the neuronal type is dependent on the GMC, the two daughter cells also acquire different fates. Cell ablation studies in the grasshopper clearly show that cell interactions between the siblings determine their respective fates (Kuwada and Goodman, 1985).

In a *Drosophila* hemisegment neuromere, the 30 named neuroblasts generate ~200 neurons including a small number (34) of motor neurons, a large number of interneurons (>150), and a few neurosecretory cells (<10). These same neuroblasts generate a large number of glial cells. Comprehensive cell lineage studies have defined the clone of neurons and glia produced by each *Drosophila* neuroblast (Schmid *et al*., 1999). These studies have identified the founding neuroblasts for all the cell types of the embryonic CNS: motor neurons, local and projection interneurons, neurosecretory cells, and glia. An important observation is that neuroblasts at similar dorsoventral positions usually generate similar cell lineages, including the same motor neuron subtype. Lineage analysis and connectivity mapping have been completed on the 31 motor neurons identified in the *Drosophila* embryo (Landgraf *et al*., 1997). Most (26 of 31) motor neurons derive from just a few neuroblasts in the ventral neuroectoderm. Although neuroblasts give rise to more than one type of motor neuron, structurally similar motor neurons generally derive from a common neuroblast and innervate operationally related muscles. This suggests a developmental mechanism linking the progeny of a specific neuroblast with a specific subset of muscles, which likely mediates formation of nerve–muscle partnerships. Despite this general principle, neurons deriving

from different neuroblast lineages can also innervate operationally related muscles, so this rule is not invariable.

2.3.2.1.3. Axonogenesis and pathfinding Growth cones lead extending axonal processes toward muscle targets. The small Rho GTPases are vital for regulation of the actin cytoskeleton dynamics that mediate growth cone extension during axonal pathfinding. In *Drosophila*, Cdc42 is involved in overall neuron morphogenesis, Rac1 is involved in axonal outgrowth and steering, and RhoA is essential for dendritic but not axonal growth (Luo *et al*., 1994; Lee *et al*., 2000; Ng *et al*., 2002). Growth cones use a complex cocktail of secreted cues and cell surface markers on epithelial cells, mesodermal cells, glial cells, and other neurons in their guidance. In the CNS, glial cells provide one of the most important guidepost functions for pioneer neurons. In the periphery, motor axons are guided by a complex combination of attractive and repulsive cues to initially select the appropriate axon tracts, then to select the appropriate point to defasciculate from this tract, and finally to select the correct target muscle within a domain of overlapping muscles. Among the best characterized of the attractive signals are members of the NCAM Immunoglobulin (IgG) superfamily (Tessier-Lavigne and Goodman, 1996), especially the Fasciclins (Bastiani *et al*., 1987; Patel *et al*., 1987; Bieber *et al*., 1989). Among the best characterized repulsive signals, are both secreted and membrane bound forms of the Semaphorin family (Kolodkin *et al*., 1993; Winberg *et al*., 1998). Many axons extend selectively along the surface of pioneer axons (Bate, 1976), forming axon bundles or fascicles, a process called selective fasciculation that requires NCAMs (Hortsch and Goodman, 1991; Tessier-Lavigne and Goodman, 1996). In addition, growth cones are guided to targets via diffusible, secreted ligands. Growth cones can also be guided by contact-dependent and diffusible repulsive signals that establish inhibitory domains.

Much of the knowledge of motor neuron guidepost cells and attractive growth substrates comes from work on the large grasshopper embryo (Hortsch and Goodman, 1991). Both glial cells and the epidermis have been shown to provide permissive, guiding substrates for pioneer axons (Bastiani *et al*., 1986; O'Connor *et al*., 1990). In both grasshoppers and *Drosophila*, the anterior corner cell (aCC) motor neuron pioneers the ISN, which carries the axons innervating the dorsal muscle field (Thomas *et al*., 1984). Later-growing axons depend on fasciculation to these pioneer axonal tracts, coupled to appropriate turning responses at distinctive choice points. These choice points are often associated with glia (Bastiani *et al*., 1986; Doe *et al*., 1986).

The initial efforts to identify the guiding molecules depended on monoclonal antibody staining screens in both the grasshopper and *Drosophila* (Hortsch and Goodman, 1991). This approach identified the surface glycoproteins Fasciclin I–IV and Neuroglian, which are each expressed on a distinctive, but overlapping set of growth cones, fascicles, and guidepost glial cells (Bastiani *et al*., 1987; Patel *et al*., 1987; Bieber *et al*., 1989; Kolodkin *et al*., 1992). Three of these proteins are members of the IgG superfamily related to vertebrate NCAM (Tessier-Lavigne and Goodman, 1996). *In vitro* aggregation studies show that these proteins function as homophilic receptors. The dynamic expression of these proteins on axons and guidepost glia is highly conserved across insect species, with similar patterns on identified motor neurons in both the grasshopper and *Drosophila* (Thomas *et al*., 1984).

In the *Drosophila* embryo, motor neurons, and the muscles they target, often express the same transcription factor prior to any contact. This paired specification is believed to drive the expression of matched homophilic receptors that will guide motor neuron pathfinding and target selection. For example, motor neurons targeting the dorsal muscles express the homeobox transcription factor *even-skipped* (*eve*), and this expression is both necessary and sufficient to guide these axons via the ISN to dorsal muscles (Landgraf *et al*., 1999b). Similarly, motor neurons targeting the ventral muscle field express the Lim-1/Isl-1/Mec-3 (LIM) homeobox transcription factor *islet*, which is sufficient to specify ventral motor axon projection (Thor and Thomas, 1997). Thus, these two genes constitute a bimodal switch regulating motor axon pathfinding to either ventral or dorsal muscle targets. The Eve transcription factor regulates the expression of NCAMs that promote adhesion to the ISN and so direct motor axons into the dorsal muscle field (Landgraf *et al*., 1999b). Misexpression of *eve* in normally ventrally projecting motor neurons will reroute them to the dorsal muscle field, bypassing their normal ventral targets. Thus, regulation of selective fasciculation is sufficient to direct motor axons towards the correct muscle group in the periphery.

What controls when motor axons leave the nerve fascicle and select specific muscle targets? One mechanism is to decrease the adhesion between motor axons, either by decreasing their NCAM expression or locally introducing repulsion. In *Drosophila*, the *beaten path* (*beat*) gene encodes

a secreted IgG superfamily protein, expressed in motor axons coincident with the period of defasciculation. In *beat* mutants, motor axons fail to defasciculate and travel past their intended muscle (Fambrough and Goodman, 1996). Moreover, misexpression of the anti-adhesive Beat protein in the dorsal-projecting *eve* expressing cells will cause them to prematurely defasciculate into the ventral muscle field (Landgraf *et al*., 1999b). Thus, it appears that Beat decreases the attractiveness of motor axons for other motor axons and directs the motor axon nerve departure choice point. A complementary mechanism that triggers defasciculation is increased adhesion to an alternative substrate, specifically muscle progenitors and target muscles. In mutants lacking muscle targets, motor axons extend into peripheral nerves, but do not defasciculate at the proper choice points (Prokop *et al*., 1996). Thus, muscles, and in particular muscle progenitors in the process of muscle formation, act to trigger proper defasciculation of motor axons (Landgraf *et al*., 1999b). One molecule that increases the adhesiveness of muscle is the *Drosophila sidestep* (*side*) gene, which encodes a novel cell surface protein (Sink *et al*., 2001). The Side protein is expressed on muscles during motor axon defasciculation and *side* mutant axons ignore their appropriate exit points and continue to extend along the motor nerves (Sink *et al*., 2001). Ectopic Side expression results in continued contact by motor axon growth cones and inappropriate pathfinding decisions. Thus, Side functions as an attractant, presumably as a ligand for an unknown receptor on growth cones. The coordinate control of appropriate adhesion and repulsion guides *Drosophila* motor axons along their peripheral routes.

2.3.2.1.4. Dendrite formation in the CNS At the same time that motor axons are pathfinding towards muscle outputs in the periphery, the dendrites of the motor neurons are similarly developing highly individual morphologies within the CNS neuropil. Compared to our knowledge of axon guidance, much less is known about the mechanisms responsible for directed outgrowth of dendrites. Very recent work has begun to examine dendrite formation in the *Drosophila* embryo and examine the partitioning of the neuropil into functionally distinct regions of dendritic arborization. The architecture of the neuropil has been mapped based on modality-specific sensory projections (Schrader and Merritt, 2000) and the scaffolding revealed by Fasciclin II expressing axonal tracts (Landgraf *et al*., 2003). Another class of reliable neuropil landmark is the constant topography of neuropeptidergic projections including Serotonin, Insulin-, FMRF-, Allatostatin-, Corazonin-, Substance-P-, and Leucokinin-1-positive neurons (Nassel *et al*., 1990; Gorczyca *et al*., 1993; Nichols *et al*., 1999; Landgraf *et al*., 2003; Taghert and Veenstra, 2003). Particularly powerful genetic mosaic strategies have been used to map the arrangement of output synapses on individual neurites in the neuropil (Lohr *et al*., 2002). These studies indicate three distinctive neuropil compartments: (1) compartments that contain primary transport pathways mostly lacking output synapses; (2) compartments that contain output presynaptic terminals; and (3) compartments that are postsynaptic. In *Drosophila*, as in other insects, the dorsal neuropil contains the arbors of efferent neurons that show little overlap with sensory projections, indicating that direct connection between sensory and motor neurons rarely, if ever, occur. Individual efferent neurons differentiate dendritic arbors in distinctive patterns (Landgraf *et al*., 1997). An important defining principle is that motor neurons that innervate muscles of similar position and orientation are often clustered and have overlapping dendritic trees.

Guidance strategies in the CNS neuropil have only recently begun to be analyzed, therefore the state of our understanding is primitive compared to motor axon targeting in the periphery. A recent surprising finding is that projections in the neuropil are controlled, at least in part, by guidance cues provided from the CNS midline rather than the target cells with which they will form synapses. In *Drosophila*, the Slit protein secreted by midline glia acts as a repellent to position axon fascicles in the neuropil at specific distances from the midline. The precise distance depends on differential combinations of the axonal Slit receptors, called "Roundabout (Robo) receptors" (Simpson *et al*., 2000). The position of dendritic arbors also depends on expression of Robo receptors responding to the same midline-derived Slit repellent (Zlatic *et al*., 2003). Robo has likewise been shown to regulate dendritic patterning and synaptic connectivity in the giant fiber system of adult *Drosophila* (Godenschwege *et al*., 2002). A recent study on cell-autonomous guidance signals showed that both Frazzled and Robo receptors on dendrites respond to diffusible signals from the midline to select their field of arborization (Furrer *et al*., 2003). It is probable that a combination of such diffusible morphogen signals and contact-dependent target signals (as yet unknown) together control dendritic pathfinding and target recognition in the CNS.

Motor neurons innervating similar muscles are often, but not necessarily, related by lineage or

position. Interestingly, however, in instances where no such developmental linkage exists, the motor neurons still share a common domain of dendritic arborization within the neuropil (Landgraf *et al.*, 1997). Thus, a general rule appears to be that muscles related by function (position and orientation) are innervated by motor neurons with a common domain of dendritic arborization, irrespective of whether the neuronal somata share a common precursor/position or not. A feature of these developing dendrites is that they express the same homophilic adhesion molecules as the axons, proteins known to mediate selective adhesion during fasciculation and target recognition. For example, motor neuron dendrites expressing the homophilic cell adhesion molecule connectin project together to the same region lateral to the anterior commissure (Nose *et al.*, 1992, 1997; Landgraf *et al.*, 2003). These parallels support the hypothesis that connectin-mediated adhesion may be another mechanism governing dendritic branching in the neuropil.

2.3.2.1.5. Target recognition and selection Identified motor neuron projections to specific target muscles were mapped first in the grasshopper, and later in *Drosophila* (Ball *et al.*, 1985; Sink and Whitington, 1991). In the grasshopper, motor neuron growth cones come into contact with muscle pioneers (see below) and show highly selective affinities for their specific targets. In *Drosophila*, similar muscle progenitors are the source of cue(s) that trigger motor axon defasciculation, targeting axons to restricted muscle fields (Landgraf *et al.*, 1999a). Subsequent to defasciculation, motor growth cones explore the forming muscle cells within the target domain, initially quite widely. But increasingly, filopodia are restricted to only a specific target myotube. When such a specific muscle target is ablated in the grasshopper, the motor axon growth cone that would have innervated it, instead continues its exploration to a more distal region (Ball *et al.*, 1985). In *Drosophila*, a combination of surgical and genetic manipulations have allowed specific muscle targets to be either duplicated or deleted in order to test targeting specificity. When ventral longitudinal muscles 6/7 are removed, for example, their motor neuron, RP3, grows past the normal target area and eventually innervates incorrect muscles in a variable pattern (Sink and Whitington, 1991). The motor growth cone terminates and differentiates into a synapse in the absence of its normal target, but only after a period of delay and continued searching. Similar observations are seen when other specific muscles are ablated (Cash *et al.*, 1992; Chiba *et al.*, 1993). Perhaps more interestingly, if a muscle target is duplicated, both muscles are innervated equally by the correct motor neuron. These observations show an extreme high level of specificity in motor axon target recognition (see also **Chapters 2.1** and **2.2**).

Motor neuron axons are guided to their proper muscles by a hierarchy of cues, starting with a neuronal transcription factor code that underlies their delivery to particular regions of the muscle field, and continuing with muscle target-specific transcription factor codes that drive the expression of defining cell surface receptors (Thor *et al.*, 1999; Odden *et al.*, 2002; see also **Chapters 2.1** and **2.2**). Different muscles express unique combinations of cell surface glycoproteins that mark them and, in at least some cases, clearly delineate the future site of motor neuron innervation in a subdomain of the myotube surface. For example, the homophilic NCAM Fasciclin III is expressed both on the RP3 growth cone and muscles 6/7, transiently at the time of target recognition (Halpern *et al.*, 1991), but is downregulated as synaptogenesis proceeds. In mutants where innervation is blocked or delayed, the myotubes still clearly express Fasciclin III in a restricted domain corresponding to the normal site of the NMJ (Broadie and Bate, 1993b). Likewise, the leucine-rich repeat (LRR) CAMs Connectin and Toll are also expressed on a small subset of muscles and the growth cones that innervate these muscles. Following target recognition, Toll is localized to synaptic sites on the muscle and downregulated (Nose *et al.*, 1992; Broadie and Bate, 1993b). These examples suggest that each muscle simply expresses a specific code of surface CAMs that allow selective adhesion with growth cones carrying a complementary set of CAMs. However, the mechanism is not simple. For example, genetic ablation of Fasciclin III, which prefigures the muscle's synaptic site prior to growth cone contact and is expressed by the growth cone during contact, does not prevent NMJ formation (Chiba *et al.*, 1995). Rather, target recognition appears, at most, only slightly impaired, consistent with the vague idea that multiple redundant recognition cues direct the first stages of synaptogenesis. Consistently, ectopic expression of these recognition factors uniformly causes more severe perturbation of neuromuscular connectivity (Chiba *et al.*, 1995). These embryonic connectivity studies have, in general, only detected a single axon innervating any muscle. However, most muscles are known to have multiple innervations in the mature larva (Keshishian *et al.*, 1996). Much of this later stage innervation is derived from the widespread terminals of ventral unpaired median (VUM) neurons, the likely source of octopaminergic type II NMJs of

larval muscles (Monastirioti *et al.*, 1995; Taghert and Veenstra, 2003). Nothing is yet known about the mechanism driving this later stage of neuromuscular target recognition and synaptogenesis.

2.3.2.2. Development of Motor Neuron Electrical Properties

Most of what we know about the electrical properties of developing insect neurons comes from studies in acutely dissociated cell cultures. In *Drosophila*, neurons developing *in vitro* from cells harvested at gastrulation, as well as cleavage arrested neuroblasts that give rise to "giant neurons" in culture, have been extensively used for defining the development of excitability and the function of genes encoding ion channels and their regulators (Solc *et al.*, 1987; O'Dowd and Aldrich, 1988; Saito and Wu, 1991; O'Dowd, 1995; Tsunoda and Salkoff, 1995a). However, after nearly two decades of *Drosophila* culture studies, spontaneous synaptic transmission between neurons *in vitro* has only recently been recorded electrophysiologically (Lee and O'Dowd, 1999, 2000), and evoked neuronal transmission has never been recorded.

This progress in fruit flies contrasts sharply with early strides made using other species. For example, limited cell migration and axon outgrowth were observed in cultured mosquito larva ganglia in 1937 (Pfeiffer, 1937) and, since then, researchers using the cockroach and other species have had great success propagating neuromuscular tissues in culture, both as explants and individual cells. The morphology, ultrastructure, and electrophysiology of these preparations (including that of NMJs formed *in vitro*) are relatively well described (Beadle and Hicks, 1985; Thomas *et al.*, 1987; Levine and Weeks, 1996). In contrast to this long history of *in vitro* studies, *in vivo* motor neuron electrophysiology in *Drosophila* has been limited to just a few recent studies, all concentrated on an accessible cluster of five motor neurons (aCC and RP1–4), and one interneuron (pCC), located in a superficial, dorsal position within the embryonic VNC (Rohrbough *et al.*, 2003). In the embryo, these identified neurons are accessible to patch-clamp recording from the cell body following removal of the overlying neurolemma with protease (Baines and Bate, 1998; Baines *et al.*, 1999).

In developing motor neurons of the *Drosophila* VNC, the first voltage-gated currents appear during mid-embryogenesis (stage 16, 13–14 h at 25 °C; ~65% embryonic development; Baines and Bate, 1998). During later embryogenesis (mid-stage 16 onwards; 70% development), motor neurons display a sequential appearance of voltage-gated ionic currents, including several outward K^+ currents, an inward Ca^{2+} current, and an inward Na^+ current (Baines and Bate, 1998; Baines *et al.*, 2001). Northern analyses show that *shaw* and *shab* transcripts encoding the I_K K^+ channels are expressed simultaneously in developing motor neurons from stage 13 (9 h at 25 °C; ~45% development; Tsunoda and Salkoff, 1995a). Consistently, the first detectable current to appear in cell body recordings is the delayed outward K^+ current (I_K). Subsequently, the calcium current (I_{Ca}) is detectable at 15 h (~70% development), the sodium current (I_{Na}) at 16 h (~75% development), and the rapidly inactivating potassium current (I_A) at 17 h (~80% development). The developmental sequence of current appearance is somewhat distinct from that seen in both *Drosophila* embryonic and pupal muscle (see below; also, Salkoff, 1985; Broadie and Bate, 1993d). Action potentials are first recorded at 17 h (~80% development), closely coincident with the appearance of I_A. By 85% development, *Drosophila* motor neurons manifest the ability to fire repetitive action potentials (Baines *et al.*, 2001).

Drosophila motor neurons exhibit multiple ligand gated receptors, although only a small subset of these have been documented *in situ*. The first ligand gated current to emerge is an ACh-gated inward cation current (I_{ACh}) during mid-embryogenesis (stage 16, 13 h at 25 °C; 62% development), at the same time that the first voltage-gated K^+ current is detectable (Baines and Bate, 1998). Picrotoxin-sensitive GABA receptors are present in cultured embryonic motor neurons (Lee and O'Dowd, 1999; Lee *et al.*, 2003), and are known to be present in *in situ* motor neurons during late embryogenesis (Rohrbough and Broadie, unpublished data), but the appearance and development of the GABA current has not been reported. Interestingly, the dorsal unpaired median (DUM) neurons of the grasshopper embryos respond to ACh (and GABA) very considerably earlier in embryogenesis (40% development), coincident with the initiation of axon outgrowth (Goodman and Spitzer, 1979). Thus, different species differ considerably in the timing of their neuronal electrical development, both in absolute terms and relative to the stage of neuronal morphological maturation.

Inhibitory GluRs are also present in *Drosophila* motor neurons, and a *Drosophila* homolog of this receptor family, expressed in oocytes, mediates a glutamate-gated chloride current (Cully *et al.*, 1996). The inhibitory glutamate-gated current is present in mature embryonic motor neurons during late embryogenesis (Rohrbough and Broadie, unpublished data), but its development has not been charted.

Endogenous activity in *Drosophila* motor neurons is first detected at 15 h (~71% development) in the form of very small (peak amplitude, 5 pA) spontaneous events that probably result from the opening of a small number of ion channels. Over the next hour, larger events (peak amplitude, 25 pA) first appear that represent synaptic currents, the first indication of synaptic transmission. The timing of the onset of synaptic function in *Drosophila* (70–75% development) is comparable to the appearance of transmission in DUM motor neurons in grasshoppers (75% development) but delayed relative to synaptic development between cercal afferents and central giant interneurons in cockroaches (55% development; Goodman and Spitzer, 1979; Blagburn *et al*., 1996). The peripheral neuromuscular junction in *Drosophila* first becomes functional just slightly early (65–70% development; Broadie and Bate, 1993e), corresponding to the time that motor neurons first display their full complement of ion channels.

2.3.2.3. Synaptogenesis in the CNS

Despite its molecular and genetic advantages, the small size of *Drosophila* has greatly hampered studies in the CNS of this species. Progress in understanding fruit fly CNS function is all very recent, and will be reviewed here. However, there is an extensive body of literature describing synaptic transmission between other insect species' neurons *in vivo* (Levine, 1984; Callec, 1985; Weeks *et al*., 1997). Most of this work focuses on mature synapses; relatively little is known about the development of CNS function.

In *Drosophila* cultured embryonic neurons, pharmacological analyses reveal that the majority of fast excitatory synaptic currents are cholinergic and mediated by nicotinic AChRs (Lee and O'Dowd, 1999, 2000). Less common inhibitory synaptic currents, mediated by picrotoxin sensitive GABA gated chloride receptors, are observed in a subset of cultured neurons. In *Drosophila* motor neurons *in situ*, the appearance of electrical currents and ligand gated neurotransmitter channels is followed closely by the onset of endogenous synaptic activity (Baines and Bate, 1998). The inputs onto these motor neurons are predominantly excitatory, cholinergic interneurons (Baines *et al*., 1999, 2001; Rohrbough and Broadie, 2002). *In situ*, both *Drosophila* motor neurons (aCC and RP2) and interneurons (pCC) exhibit infrequent fast, spontaneous events after 16 h (~75% of development; Baines and Bate, 1998), and then subsequently sustain inward currents supporting APs after 19–20 h (Baines *et al*., 1999, 2001). Both of these types of endogenous activity require external Ca^{2+}, and are reduced/eliminated by mutations that block AP firing, deplete SV supplies, or specifically eliminate cholinergic transmission, thus indicating that they represent cholinergic synaptic input (Baines and Bate, 1998; Baines *et al*., 1999, 2001). By 18–19 h at 25 °C (85–90% of development), synaptic input to motor neurons is present in the form of both fast AP mediated synaptic currents and periodic, sustained (up to 1 s duration) episodes of excitatory input occurring at least several times per minute (Baines *et al*., 1999, 2001). This sustained, "rhythmic" excitatory activity requires cholinergic synaptic input, since it is eliminated by conditionally blocking ACh synthesis in cholinergic interneurons (Baines *et al*., 2001). Sustained bouts of cholinergic input activate large excitatory potentials accompanied by bursts of AP firing in the motor neuron (Rohrbough and Broadie, 2002; Rohrbough *et al*., 2003). The output of this centrally generated motor activity is manifest at the NMJ as periodic bursts of high-frequency glutamatergic transmission to drive the peristaltic muscle contraction underlying coordinated locomotion (Broadie and Bate, 1993a; Baines *et al*., 2001; Cattaert and Birman, 2001).

In *Drosophila*, motor neurons develop in the absence of CNS synaptic transmission without any apparent change in synaptic connectivity (Baines *et al*., 2001). Although it is difficult to be certain that central synapses do not form in inappropriate areas under blockade conditions, it seems probable that there is no requirement for synaptic activity in establishing central synapses. In the absence of synaptic transmission, however, motor neurons do develop slightly abnormal basal electrical properties, including greater voltage activated Na^+ and K^+ currents, which result in altered neuronal excitability (Baines *et al*., 2001). The increased currents appear to be due, at least in part, to upregulated expression of *para* (I_{Na}) and *slowpoke* ($I_{K(Ca)}$)(Rohrbough *et al*., 2003). When neurotransmission is blocked, the number of action potentials fired by a depolarizing voltage ramp (−60 to +60 mV) is increased, and the amplitude of the initial action potential is significantly larger. The modulation of neuronal electrical properties is not permanent, but rather can be reversed by restoration of synaptic function. This finding suggests that synaptic transmission has at least some role in regulating the development of electrical properties. Somewhat surprisingly, eliminating synaptic transmission selectively in motor neurons, rather than globally as above, does alter synapse formation onto these cells (Baines *et al*., 1999). Ultrastructural analyses reveal fewer presynaptic input sites and a lower frequency of endogenous synaptic events onto synaptically silenced *Drosophila* motor neurons (Baines *et al*., 1999).

These results suggest that synaptic output by the postsynaptic motor neuron regulates synaptogenesis by interneurons onto these cells. Why might pan-neuronal transmission blockade cause different effects than selective blockade only in a few motor neurons? Perhaps CNS competition between neurons is a decisive factor in regulating circuit formation in the *Drosophila* embryo. A similar mechanism in mammals is central to synapse assembly in systems ranging from retinotectal projections to motor terminals.

In addition to its role in axon fasciculation (above), the homophilic NCAM Fasciclin II operates to stabilize synaptic connections and mediate activity dependent plasticity in the postembryonic NMJ (Schuster *et al.*, 1996a, 1996b; Davis *et al.*, 1997; Davis and Goodman, 1998). At the NMJ, Fasciclin II is expressed in pre- and postsynaptic cells from early stages of synaptogenesis, although it is not required for synapse formation (Schuster *et al.*, 1996a, 1996b). In contrast, overexpression of Fasciclin II in embryonic muscle can initiate ectopic synapse formation, suggesting that postsynaptic Fasciclin II may be limiting during synaptogenesis (Davis *et al.*, 1997; Davis and Goodman, 1998). Based on these findings, the role of Fasciclin II in CNS synaptogenesis was examined, and it was shown that Fasciclin II acts as an important determinant of central synapse regulation (Baines *et al.*, 2002). As observed at the NMJ, synaptogenesis by identified neurons in the embryonic CNS does not require Fasciclin II, but the postembryonic elaboration of these synaptic connections is impaired in the absence of Fasciclin II. In addition, just like the NMJ, central synapses are highly sensitive to alterations in the balance of Fasciclin II between pre- and postsynaptic cells. Increasing Fasciclin II in either cell during embryogenesis disrupts synaptic connectivity, causing defects comparable to the targeted blockade of synaptic transmission (Baines *et al.*, 2002). In contrast to the findings at the NMJ, however, and to work on the Fasciclin II homolog in the mammalian hippocampus, elevated Fasciclin II reduces the number of functional synapses in the *Drosophila* CNS. Thus, in flies, Fasciclin II is not required for synaptogenesis but can regulate the elaboration of synaptic contacts, especially during postembryonic development, in a synapse-type specific manner.

2.3.3. Development of Glial Function

2.3.3.1. Central Glia and CNS Scaffolding

Compared to neurons, relatively little has been revealed so far about the functional development of glial cells in insects, although their importance for insect development has long been recognized (Anderson *et al.*, 1980; Oland and Tolbert, 2003). Many classes of glial cells (glia) have been identified in insects. Two major classes include: (1) glia that surround or enclose neuronal cell bodies and (2) glia that first prefigure and later wrap around axon tracts (Jacobs and Goodman, 1989). In the CNS, a prominent set of glia exist at the midline. One subset of midline glia act as the source of signals that attract (Netrin) and repulse (Slit) motor axons from crossing the midline, and thus determine ipsilateral versus contralateral motor axon projections. The Slit signal working on related Roundabout receptors (Robo I, II, and III) also determines the lateral distance traveled prior to axonal turning into discrete fascicles. As discussed above, Slit signaling also plays a role in establishing dendritic domains relative to the CNS midline. A separate subset of midline glia mediate contact-dependent guidance and, later, insulation functions.

In *Drosophila*, six midline glia per hemisegment are characterized by unique gene expression patterns, and mutation of these genes reveal critical axonal guidance functions (Klambt *et al.*, 1991; Hidalgo, 2003). These six glia first prefigure the future path of the axons, just before axons are extended. These cells continue to divide and, in later stages, enwrap the longitudinal axonal connectives in the CNS. Many other glia are not associated with axons but rather reside in the cell body layers in direct contact with the neuronal soma. The role of these glial cells is not well established. The mesodermally derived belt glia extend circumferentially around the CNS, generating a tough enclosing sheath that acts as a blood–brain barrier to chemically isolate the CNS from the rest of the body.

Recent work in *Drosophila* has begun to systematically reveal genes specific to glial cell functional development. A genomic screen utilizing *glial cells missing* (*gcm*, a gene encoding a protein that determines whether cells assume glial or neuronal fates, Jones *et al.*, 1995; see also below) mutants, has identified >80 new *Drosophila* genes with expression restricted to glia (Freeman *et al.*, 2003). These genes show expression patterns varying from pan-glial, through peripheral/CNS specific, to select subpopulations of glia. This work shows that a midline-derived netrin signal orients glia cell migration via a repulsive netrin receptor (dUnc-5), and *draper*, one of the newly identified genes, mediates glial wrapping (Freeman *et al.*, 2003; see also below). Importantly, many (>80%) of the identified genes have close homologs expressed in corresponding sets of mammalian glia, indicating conserved molecular bases of glial function.

2.3.3.2. Peripheral Glia and Motor Neuron Pathfinding

Peripheral glia arise from the neural crest in vertebrates and the lateral edge of the CNS in insects. Peripheral glia in *Drosophila* are molecularly distinct from CNS glia. Both express unique proteins, such as gliotactin in the peripheral glia (Auld *et al.*, 1995), and wrapper in the central glia (Noordermeer *et al.*, 1998). In *Drosophila*, each hemisegment neuromere has two peripheral nerve roots, by which motor axons exit and sensory axons enter the CNS. Several classes of glial cells are associated with these peripheral nerves at different points. First, there are a small number of glial cells associated with the segmental (middle of neuromere) and intersegmental (neuromere boundary) nerve roots, where they diverge from the main CNS axonal tracts. These cells are present prior to axon extension, and ablation of this glial class in the grasshopper prevents formation of the peripheral nerve (Bastiani *et al.*, 1986). Second, the so-called "exit glia" are located just outside the CNS, where the segmental and intersegmental neurons diverge into peripheral axonal pathways. In addition, there are several glial cells that associate with peripheral axonal pathways, and enwrap the axons once the paths have been established.

Most peripheral glia are born in the CNS near the lateral exit points for the peripheral nerves. Lineage analyses in *Drosophila* have shown that approximately 8–10 (some variation) peripheral glia per hemisegment arise specifically from neuroblasts 1–3 and 2–5 (Schmid *et al.*, 1999; Sepp *et al.*, 2001). At least one further glial cell is born in the periphery, associated with the ISN, and remains in its birth place through later development (Hidalgo, 2003). During mid-embryogenesis, the centrally born glia migrate over great distances to their final peripheral locations. These cells migrate as a continuous chain of glia, with the pioneering glial cells actively exploring the environment using Actin-based filopodia (Sepp and Auld, 2003). The small GTPases RhoA and Rac1 mediate the Actin cytoskeletal rearrangements required for this migration (Sepp and Auld, 2003).

In the CNS, the immature glia seem to act as intermediate guidepost cells for pioneer motor axons migrating into the periphery. Peripheral glia prefigure axon paths through the CNS/periphery transition zone through which axons migrate into and out of the CNS. When peripheral glia are ablated early, via targeted expression of the cell death genes *grim* and *ced-3*, motor axon trajectories are initially perturbed, although later largely corrected (Sepp *et al.*, 2001). This suggests that peripheral glia do act as early guideposts for motor axons, but that other cues in the periphery are sufficient to guide these axons to their correct target muscles. Sensory axons entering the CNS are also disrupted, but these pathfinding errors are not corrected (Sepp *et al.*, 2001). Following this early guidance, motor axon growth cones extend past the immature glia and begin to pathfind into the developing muscle field. At this point, these motor axons appear to now serve as the guidance substrate for the migration of glial cells into the periphery (Sepp *et al.*, 2000). For example, in *Drosophila*, the aCC neuron pioneers the ISN during stage 12 (~40% development). Once it has passed the 8–10 glia at the CNS exit point, the glia begin to follow the aCC axon into the periphery (Sepp *et al.*, 2000). Importantly, the glial growth cones never appear to extend past the aCC pioneer growth cone, suggesting that the aCC is acting as the substrate for glial cell migration. During stages 13–15 (47–60% development), the peripheral glia first follow the outgrowing motor axons through the ventral field, and then the mixed motor/sensory axons, through the dorsal field (Sepp *et al.*, 2000).

In *Drosophila*, genetic mutations that impair glial differentiation result in profound defects in peripheral nerves. For example, mutations in the homeobox transcription factor *gcm* gene disrupt the specification of most glia and cause severe axonal defasciculation and pathfinding errors (Jones *et al.*, 1995). However, these mutations affect all glial cells, not just the peripheral glia selectively, so the cause of these defects is uncertain. Ablation or genetic disruption of peripheral glia results in defasciculated axon tracts (Sepp *et al.*, 2001), but it has yet to be genetically proven that peripheral glia mediate axonal pathfinding. Indeed, the developmental profile given above suggests the opposite: in peripheral axons, first motor axons ventrally and then sensory axons dorsally provide guidance for the peripheral glia to reach their mature destinations.

2.3.3.3. Glial Wrapping of Peripheral Axons

During migration from the CNS to their final peripheral destinations, glial cells already begin to extend processes that enwrap surrounding motor and sensory axons. Although considerable glial wrapping occurs during the last several hours of *Drosophila* embryogenesis, glia do not entirely wrap motor axons in the embryo, and the terminal ends of motor axons remain unsheathed at hatching (Auld *et al.*, 1995; Sepp *et al.*, 2000). This suggests that peripheral glia are not directly involved in the generation of neuromuscular contacts or the establishment

of functional NMJs. During postembryonic development, peripheral glia continue to extend cytoplasmic process, until axonal wrapping is complete and glial processes extend completely to the NMJ (Sepp *et al.*, 2000). The glial ensheathment surrounds all the axons on the nerve fascicle in a single bundle, insulating a common axonal compartment from the surrounding hemolymph. This process occurs gradually over the first and second instar stages, and yet must be remarkably rapid to keep up with the impressive rate of larval growth. All wrapping in larvae appears to be due to extension of existing glial processes, since further glial division does not appear to occur in postembryonic stages (Sepp *et al.*, 2000). By the third instar, glial processes extend completely to the NMJ. In both type I and type II NMJs, glial processes are usually observed extending to the first bouton on the synapse, although never beyond this point (Sepp *et al.*, 2000).

Glial cells regulate neural activity by insulating neurons and controlling the axonal microenvironment. Peripheral glia help maintain the appropriate ionic environment to facilitate AP propagation in motor axons. In insects, for example, peripheral glia shield axons from the high K^+ concentration in the hemolymph, which would be predicted to largely abolish neuronal excitability. Little is known about the molecular mechanisms underlying glial wrapping of axons. However, a *Drosophila* mutant named *fray* has revealed a novel class of serine/threonine kinase in peripheral glia required for axon ensheathment (Leiserson *et al.*, 2000). The *fray* mutants do not ensheath peripheral axons properly, leading to axonal defasciculation and early larval death (Leiserson *et al.*, 2000). In normal embryos, the tight glial barrier is maintained by septate junctions between glial cells, which serve the function of vertebrate tight junctions to maintain a selective-diffusion barrier. Tight junctions are absent in insects. *Drosophila* has two types of septate junction (SJ), smooth (sSJs) and pleated (pSJs) (Campos-Ortega and Hartenstein, 1997). There are five characterized SJ associated proteins in *Drosophila*, all with clear roles in SJ formation: Gliotactin (Gli), Neurexin IV (Nrx), Discs large (Dlg), Scribble (Scrib), and Coracle (Cora). Mutation of any of these genes disrupts SJ formation (Woods and Bryant, 1993; Auld *et al.*, 1995; Baumgartner *et al.*, 1996; Bilder *et al.*, 2003). Gli is a cholinesterase-like molecule (noncatalytically active) that is a member of a class of adhesion proteins termed Electrotactins (Auld *et al.*, 1995; Schulte *et al.*, 2003). Nrx is a transmembrane protein, primarily characterized as a synapse associated protein (Baumgartner *et al.*, 1996). Neurexins were first identified as synaptic receptors for Latrotoxin, the component of black widow spider venom that triggers massive exocytosis, and are thought to be involved in presynaptic differentiation in vertebrates (Scheiffele *et al.*, 2000). Dlg and Scrib are membrane associated PSD-95/Dlg/ZO-1 (PDZ) domain containing proteins that act as multiprotein complex scaffolds (Woods and Bryant, 1993; Bilder, 2001; Bilder *et al.*, 2003). Cora is a Band 4.1 homolog with a four point One/Ezrin/Vadixin/Moesin protein–protein interaction domain that associates Band 4.1 protein attaches the cell cytoskeleton to transmembrane signaling proteins.

Gliotactin is expressed throughout the processes of peripheral glia in late embryos and larvae and is required for the formation of the peripheral blood–nerve barrier (Auld *et al.*, 1995). In *gli* mutants, peripheral glia develop normally at the light microscope level, but ultrastructurally they contain small gaps in the glia–glia cell interfaces, compromising the peripheral blood–nerve barrier. This can be shown experimentally by exposing a nerve to an electron-dense dye, which is completely excluded from the axonal compartment in normal embryos but penetrates the impaired glial sheath of the mutants (Auld *et al.*, 1995). In *gli* mutants, the high $[K^+]$ hemolymph also contacts motor axons, action potentials fail to propagate, and the embryos are paralyzed. Low $[K^+]$ saline rescues both action potential propagation and movement (Auld *et al.*, 1995). Furthermore, in *gli* mutants, Nrx, Dlg, and Cora expression is strongly perturbed. In contrast to the other SJ mutants, SJ are present in *gli* mutants, but are morphologically immature (Schulte *et al.*, 2003).

Neurexin IV (Nrx) localizes to septate junctions in peripheral and subperineural glial junctions (Baumgartner *et al.*, 1996). As in *gli* mutants, *nrx* mutants maintain peripheral glial cells that look normal at the light microscope level. However, ultrastructural examination reveals that *nrx* mutants lack the glial–glial SJs that are required to maintain the tight blood–nerve–brain barrier. As a result, *nrx* mutants, like *gli* mutants, lack action potentials and are paralyzed (Baumgartner *et al.*, 1996). Loss of Nrx causes the mislocalization of Cora, the *Drosophila* protein 4.1 homolog, and eliminates ultrastructurally defined SJs.

Another member of the Neurexin protein superfamily is encoded by the *Drosophila axotactin* (*axo*) gene (Yuan and Ganetzky, 1999). Unlike the transmembrane proteins described above, Axo is secreted by glia and subsequently localized to axonal tracts. Mutations in *axo* are temperature sensitive; at 37 °C, action potentials are blocked (Yuan and Ganetzky, 1999). However, the blood–nerve–brain barrier is

intact in *axo* mutants. This suggests that Axo is a component of a glial–neuronal signaling pathway that acutely regulates the electrical properties of target axons.

To summarize, these results demonstrate that insect glial cells are vital for the acute maintenance of neuronal signaling. Defined glial functions include: (1) glial wrapping to insulate motor axons from the ionic composition of the hemolymph and (2) glial-neuronal communication required to develop or maintain neuronal signaling properties.

2.3.4. Development of Muscle Function

2.3.4.1. Muscle Morphogenesis and Patterning

2.3.4.1.1. Early myogenesis Fate-mapping techniques place the primordial cells of mesodermal structures, prominently including the somatic muscles, in the midventral regions of the blastoderm embryo. These cells will become mesoderm, but they do not appear to possess any finer fate restriction at this stage. Thus, zygotic gene expression in the blastoderm defines the mesodermal anlage, but later information is required to specify precise developmental pathways, such as those leasing to development of fat body, heart, blood, somatic, and visceral muscle (see also **Chapters 2.1**, **2.2**, **2.6**, and **2.9**). During gastrulation, presumptive mesodermal cells move into the interior of the embryo along the invaginating ventral furrow. This embryonically defined germ layer corresponds with a distinctive domain of gene expression (e.g., *twist* and *snail*). Twist (basic HLH transcription factor) and Snail (zinc finger transcription factor) are required for the formation of the mesoderm as mutants in both genes fail to form any mesodermal derivatives. Twist activates many mesoderm specific genes, whereas Snail suppresses the expression of nonmesodermal genes (Leptin, 1991; Casal and Leptin, 1996). Different domains of Twist expression (high and low) are apparent in the mesoderm following gastrulation, and the somatic (body wall) muscles are derived from only the high [Twist] domains. Twist drives the transcription of the *Drosophila* homolog of myocyte enhancer factor (dMef2), an essential regulator of the myogenic pathway from the mesoderm (Baylies and Bate, 1996; Artero *et al*., 1998).

In extended germ band embryos, such as *Drosophila*, the patterning of the mesoderm takes place beginning at the period between gastrulation and germ band retraction. This period is characterized by migration, proliferation (cell division), and restructuring of the mesodermal progenitor cells. Invaginating cells appear to be committed to mesodermal fates at the time of gastrulation, but their specific fates within the mesoderm are still labile at this time. Numerous waves of mitosis occur in the mesoderm (at least four rounds of division in *Drosophila*), with the final divisions continuing during late germ band retraction and soon after shortening is completed. The exact number of cell divisions seems to vary widely between different progenitor cells. Mesodermal cells begin to acquire specific differentiated fates just prior to or at the time of germ band retraction. Cell transplantation studies indicate that the fate of a mesodermal cell is dictated by its position within the invaginated mesoderm and by its final position relative to the embryonic ectoderm.

Following migration, mesodermal cells form a thin sheet covering the inner surface of the developing ectoderm. Classic experiments performed in the 1940s to 1950s on beetle and lacewing embryos indicated that mesodermal fates are dependent on the adjacent ectoderm. These studies suggested that early mesodermal cells are equivalent until fate restrictions are dictated by the ectodermal cells they come in contact with. Genetic studies in *Drosophila* have revealed two important ectodermal signals: Decapentaplegic (Dpp), a transforming growth factor-β protein, and Wingless (Wg), a Wnt signaling protein. Dpp acts as an inductive signal to divide myoblasts into dorsal and ventral domains, whereas Wg appears to regulate Twist levels and is required for the specification of the majority of muscles (Staehling-Hampton *et al*., 1994; Baylies *et al*., 1995; Riechmann *et al*., 1997).

The formation of somatic muscles is first detectable during germ band retraction. The somatic mesoderm gives rise to myoblasts that have the capacity to fuse with appropriate neighboring cells. Nascent syncytia, formed when myoblasts begin to fuse, first appear ventrally, immediately adjacent to the developing CNS, at the onset of germ band retraction (Bate, 1990). As germ band retraction continues, myoblasts fuse with syncytia in lateral and dorsal locations. Each developing syncytial myotube continues to enlarge via fusion with neighboring myoblasts, so that the syncytia rapidly become more prominent while the pool of unfused myoblasts dwindles. Myoblast fusion continues for several hours, with the size of individual myotubes dictated by the number of fusion events (Bate, 1990). For any given muscle, the number of nuclei is tightly controlled but is not invariant. While fusion continues, and following its completion, the enlarging myotube extends growth cone-like processes that reach over the surface of the epidermis and probe for attachment sites (Bate, 1990). By ~60% embryonic development in *Drosophila*, muscle assembly

appears complete: fusion events stop and muscles are attached to the epidermis to form the specific muscle field pattern. The end of muscle assembly coincides with the arrival of motor neuron growth cones exploring the surface of the myotubes in preparation of forming NMJs. Innervation plays no part in establishing or maintaining the muscle pattern (Broadie and Bate, 1993c).

Myoblast fusion is a multiple-step process involving initial cell recognition/adhesion, formation of a prefusion complex, plaque formation, and, finally, plasma membrane fusion driving to myotube formation. This cellular process appears well conserved between *Drosophila* and vertebrates. Genetic analyses in *Drosophila* have identified a growing number of genes specifically required for myoblast fusion. The *rolling stone* (*rost*) gene, for example, encodes an adhesive transmembrane protein involved in the early stages of myoblast recognition/adhesion and development of the prefusion complex (Frasch and Leptin, 2000). The *myoblast city* (*mbc*) gene encodes a homolog of human DOCK180, and functions as an upstream regulator of the Rho family GTPase Rac1 (Rushton *et al*., 1995; Frasch and Leptin, 2000). The *blown fuse* (*blow*) gene encodes a cytoplasmic protein required for progression between intercellular recognition/adhesion and formation of the prefusion complex (Doberstein *et al*., 1997). The *titin* gene encodes an enormous elastic protein known to regulate cytoskeletal scaffolds. During myoblast fusion, Titin organizes cytoskeletal elements required for formation of membrane plaques between prefused cells, and later controls organization of the contractile cytoskeleton (Zhang *et al*., 2000).

2.3.4.1.2. Establishing muscle identity *Drosophila* syncytial muscles form a precise pattern. Each muscle has a unique identity defined by its size (number of nuclei), shape (arrangement of epidermal attachment sites), and pattern of innervation (Bate *et al*., 1999). This identity is presumably determined by transcription factor cascades that trigger expression of slightly different sets of genes, such that each muscle cell displays a specific number of myoblast fusion events and a set of cell surface proteins. Depending on the cell surface proteins they express, myoblasts recognize the appropriate attachment sites on the epidermis and the appropriate innervating neurons extending from the CNS. Consistent with this hypothesis, a small number of spatially restricted transcription factors have been identified (Michelson *et al*., 1990; Riechmann *et al*., 1997; Carmena *et al*., 1998) that define small subsets of myotubes from the onset of myogenesis. In several cases, the expression of these transcription factors is restricted to a single myoblast, but expression extends to subsequent nuclei following fusion. These observations suggest that unique cells may be specified based on position, provided an identity based on expression of one or more distinguishing transcription factors, and endowed with the power to recruit neighboring myoblasts through fusion and subsequent influence of gene expression (see also **Chapters 2.1** and **2.2**).

The founder cell hypothesis for establishing muscle identity was proposed by Michael Bate in 1990 (Bate, 1990). In this model, the essential step in crystallizing the muscle pattern is a process that selects a unique "founder cell" for each muscle in every segment. In *Drosophila*, 30 founders are specified for the 30 muscles in an abdominal hemisegment. The founder cells have the ability to initiate fusion with the surrounding cloud of myoblasts and are, thus, termed "fusion-competent" cells. These cells are proposed to be naive or equivalent myoblasts that are subsequently entrained to a particular muscle identity only following fusion with a founder cell myoblast. Muscle founder cells express combinations of transcriptional regulators that confer a specific identity, such as Krüppel (Kr) and S59/Slouch (Slou) (Ruiz-Gomez *et al*., 1997; Baylies and Michelson, 2001). The *dumbfounded* (*duf/kire*) gene is expressed only in founder cells, and its product acts as an attractant or adhesive required to initiate fusion with fusion-competent cells (Ruiz-Gomez *et al*., 2000). Ectopic expression of *dumbfounded* causes inappropriate cellular fusion, indicating that this protein alone confers the ability in founder cells to initiate fusion. The expression of genes such as *sticks and stones* (*sns*) and *myoblasts incompetent* (*minc*) is restricted to fusion-competent cells, suggesting they are a selected population of cells determined by distinctive regulatory mechanisms (Ruiz-Gomez *et al*., 2002). In the absence of these genes, myoblasts fail to fuse and remain as an arrested population of mesodermal cells (see also **Chapters 2.1** and **2.2**).

Although derived primarily from observations in *Drosophila*, this founder cell hypothesis was influenced by earlier work in grasshopper embryos. Cell ablation studies in the grasshopper have shown that muscle progenitors, called "muscle pioneers," are uniquely identifiable cells containing fate restriction to become specific muscles (Ho *et al*., 1983; Ball *et al*., 1985). In the grasshopper, muscle pioneers are distinctive large cells that extend growth cones to define the mature muscle placement, and subsequently fuse with neighboring myoblasts to form the syncytial myotubes. Ablation studies have shown

that removal of a pioneer results in the loss of the muscle, despite the fact that the bulk of the fusion-competent myoblasts remain in place (Ball and Goodman, 1985a, 1985b). In *Drosophila myoblast city* mutants that block fusion, founder cells act similarly to grasshopper pioneer cells in spanning the area of the future muscle and otherwise acquiring the mature muscle properties (Rushton *et al.*, 1995; Prokop *et al.*, 1996). Thus, the founder cell hypothesis proposes that unique cells, founder cells in *Drosophila* and muscle pioneers in the grasshopper, seed the muscle pattern and are irreplaceable for the specification of muscle identity. In *Drosophila*, the adult muscles appear seeded in a similar way. When *twist* expression declines rapidly following the onset of germ band retraction, it leaves behind a small subset of *twist* expressing cells as isolated single cells associated with the developing PNS (Bate *et al.*, 1991). These single cells divide starting in early larval stages to form the progenitors for specific subsets of adult muscles (Broadie and Bate, 1991; see also **Chapter 2.2**).

There are considerable parallels between the specification of muscle founder cells and neuroblast specification in the developing nervous system. As in the nervous system, the earliest indication of muscle specification is the appearance of "competence domains" expressing the proneural gene *lethal of scute* (*l(1)sc*) (Carmena *et al.*, 1995, 1998). As in the nervous system, each muscle competence group gives rise to a single progenitor (the founder cell), which specifies a specific muscle in the mesoderm. Furthermore, as in the nervous system, the Notch signaling pathway blocks all other cells from adopting the founder cell fate (lateral inhibition mechanism). In neurogenic mutants, the number of founder cells in the mesoderm, defined by patterns of gene expression, is dramatically increased. Rather than discrete individual cells, clusters of presumptive founder cells are observed at similar positions in the developing mesoderm (Ruiz-Gomez *et al.*, 1997). Thus, as in the nervous system, neurogenic genes appear to act in a lateral interference mechanism to select a specific muscle founder cell from a group of competent cells.

2.3.4.1.3. Development of muscle integrity Prior to recognition of the muscle target by the motor axon growth cone, *Drosophila* myoblast fusion is complete and the newly formed syncytial myotubes have finalized their attachments to the epidermis, generating the mature muscle pattern. Consistent with this timing, the arrest of motor axon outgrowth does not alter the development of the muscle pattern (Broadie and Bate, 1993c). However, at this stage (12–13 h at 25 °C; ~60% embryonic development), myotubes are extensively electrically and dye-coupled together into large multifiber networks, but lack individual integrity (Broadie and Bate, 1993e). Myotubes are interconnected to their neighbors via extensive cytoplasmic bridges, surrounded by thin, patchy basal laminae (Rheuben *et al.*, 1999). Coupling occurs between myotubes of different positional classes (longitudinal, transverse, oblique) within a hemisegment, as well as, strangely, across segmental borders. It is not clear how cytosolic bridges span the segmental boundaries. The purpose of the extensive connectedness of developing myotubes is not known either, but it may aid in intercellular communication or help to maintain synchronous myogenesis within and between segments.

During early stage 16 (13–14 h at 25 °C; 62–65% development), *Drosophila* myotubes abruptly and synchronously uncouple (Broadie and Bate, 1993e). This uncoupling coincides with the contacts between myotubes and motor neuron partners. Uncoupling also appears to coincide with the onset of electrogenesis in the myotubes (Broadie and Bate, 1993d). However, because it is difficult to effectively voltage-clamp the coupled myotubes, it is formally possible that currents may be initiated at earlier stages. In the absence of innervation, myotubes uncouple at the correct time and to the correct extent, and the appearance and maturation of muscle electrical properties is not detectably perturbed (Broadie and Bate, 1993d). Therefore, uncoupling is not due to instruction from the motor neuron.

After uncoupling, detectable dye transfer is restricted to <10% of dye injected myotubes, a figure that remains relatively constant for the remainder of embryonic and larval development (Ueda and Kidokoro, 1996). Although relatively strong electrical coupling between myotubes persists through maturity, tight voltage-clamp of individual myotubes is now readily accomplished. At maturity, the intersegmental coupling coefficients between muscles 6 and 7 remain high (range of 0.33–0.43), although coupling with other muscles within the segment is much lower or undetectable (Ueda and Kidokoro, 1996). Coupling of adjacent muscle 6 cells between segments (intrasegmental coupling) is still reliably detected (coupling coefficient of 0.16). The purpose of muscle electrical coupling is unknown, but it may be to aid the coordination of muscle contraction during locomotion, particularly between muscles acting like a single functional unit, such as the ventral longitudinal muscles 6 and 7.

In the *Drosophila* neuromusculature, as in the neuromusculature of other insects (Walther, 1981), the myotubes appear to actively engage in guiding

motor axons to the correct target area of innervation (Bate, 1990). Myotubes extend dynamic Actin-based processes towards the filopodia of the motor axon prior to contact. The resemblance of the two motile projections has led to the term "myopodia" to describe the myotube processes (Ritzenthaler *et al*., 2000). Following the completion of myoblast fusion, myopodia appear to extend randomly from the myotube, but as they contact and court the motor axon filopodia, they become progressively restricted to the developing site of innervation. This restriction to the innervation site is due to interaction with the neuronal growth cone, as myopodia clustering does not occur in the absence of motor neuron outgrowth (Ritzenthaler *et al*., 2000). It is unclear whether restriction of myopodia to the innervation site is due to instruction from the motor axon growth cone or reflects mutual interactions between the synaptic partners. However, genetic manipulation of the expression of the myotube proteins α-Integrin (PSII) and Toll, which regulate synaptic adhesiveness, reduces the frequency of myopodia clustering during innervation (Ritzenthaler and Chiba, 2003). It was, therefore, suggested that myopodia clustering is due to the adhesion between a subset of myopodia and filopodia of the innervating growth cone, which maintains these processes while the others are eliminated. Although these observations show that myopodia join filopodia in a dynamic dance during target recognition, there is as yet no indication of the role myopodia play in this process, or even whether they are required for neuromuscular synaptogenesis.

2.3.4.2. Development of Muscle Electrical Properties

The first intracellular recordings from insect muscle (and functional characterization of insect neuromuscular transmission) was published in 1953 by Castillo, Hoyle, and Machne (Castillo *et al*., 1953). Since then, insect muscles have been the subject of many detailed electrophysiological studies, and a large body of literature exists that describes these findings (Ashcroft, 1982; Aidley, 1985). Few of these studies have sought to understand development of neuromuscular transmission, however, or sought to trace changes in electrical properties over time (Saito and Kawai, 1987; Rose *et al*., 2001; Keyser *et al*., 2003). The relevant findings from *Drosophila* are reviewed below.

As mentioned earlier (Section 2.3.1.1.3), five voltage-gated currents are present in the larval muscles; an inward Ca^{2+} current (I_{Ca}), two outward K^+ currents (I_A, I_K), and two outward Ca^{2+} dependent K^+ currents (I_{CF}, I_{CS}) (Singh and Wu, 1999). These currents mature in a rapid sequential order and are first detectable at the time that the myotubes uncouple during early stage 16 (~62% embryonic development), when muscles can first be reliably voltage-clamped (Broadie and Bate, 1993a, 1993d). Apparent already when the myotubes uncouple, is a small inward, voltage-gated I_{Ca}. Initially, this is the only current apparent in voltage step recordings, indicating that it is the first voltage-gated current present in embryonic muscle (Broadie and Bate, 1993c, 1993d). A stretch-activated, outward K^+ current is also recordable as soon as myotubes uncouple, and this persists throughout later development. Within 1 h of myotube uncoupling, at ~14 h (~66% development), outward voltage-gated K^+ currents appear in the myotubes. Two distinct classes of K^+ current appear at the same time: (1) a delayed, noninactivating K current (I_K) and (2) a rapid-onset, rapidly inactivating A current (I_A) (Broadie and Bate, 1993d). Finally, much later in embryogenesis, during mid-late stage 17 (~18 h at 25 °C; ~85% development), calcium-dependent K^+ currents appear. Again, two distinct classes of current are first detectable at or close to the same time: (1) a rapid, inactivating I_{CF} and (2) a delayed noninactivating I_{CS} (Broadie and Bate, 1993e).

The developmental profile of these different myotube currents is specific for each class of current and very different between currents. I_{Ca} is already quite robust and easily detectable when the myotubes uncouple, and its amplitude increases gradually but continuously throughout embryogenesis; at hatching, the I_{Ca} current peak amplitude has approximately doubled (Broadie and Bate, 1993c, 1993d). In contrast, the amplitude of the K^+ currents increases much more rapidly soon after their appearance. The I_K current climbs quickly in the first 2 h following myotube uncoupling, then levels off to a relatively gradual increase for the rest of embryogenesis (Broadie and Bate, 1993d). The I_A current climbs much more rapidly showing a dramatic increase in amplitude soon after myotube uncoupling at ~18 h (~85% development). At this point, I_A has peaked and shows no further increase through hatching (Broadie and Bate, 1993d). The late appearing calcium-gated K^+ currents are small relative to the other currents, and display a gradual rise in amplitude during the last hours prior to hatching. As a result of these developmental profiles, the voltage-gated K^+ currents dominate the myotube current profile throughout embryonic myogenesis, with the I_A current having the largest amplitude and the I_K current having the second largest. In whole cell recordings, the inward I_{Ca} current is masked by these outward K^+ currents

but, when the K^+ currents are removed, the I_{Ca} is revealed to be robust and have the third greatest amplitude. The calcium-gated K^+ currents contribute only marginally to the myotube current through the end of embryogenesis. Development of these currents in postembryonic muscles has not been reported.

The timing and order of appearance of currents in myotubes differs from motor neurons. In general, electrogenesis in neurons is delayed, albeit relatively slightly, relative to myotubes. In both cases, I_{Ca} and I_K are the first currents to appear, nearly synchronously, but the order of their very earliest detection is reversed in neurons relative to myotubes. In neurons, the next current to appear is I_{Na}, which is not present in insect muscles. Finally, I_A appears markedly later in neurons than in muscles. In neurons, the appearance of I_A coincides with the first action potentials (see above). The Ca^{2+} dependent K^+ currents have not been reported in embryonic neurons, either because they are not yet present or are not easily detectable. In embryonic muscles, the Ca^{2+} dependent K^+ currents are the last to appear (just prior to hatching), and remain very small and relatively hard to detect.

The properties of currents in embryonic myotubes appear similar to currents in mature larval muscle. The notable exception is the embryonic I_A current. During early myogenesis, prior to 14 h at 25 °C (<65% development), the I_A current has a midpoint of steady-state inactivation 40 mV more negative than in the mature embryo or larva (Broadie and Bate, 1993d). An I_A current with this inactivation gate should be entirely inactivated at the normal embryonic myotube resting potential of ~ -60 mV. Experimentally, a prolonged, negative voltage prepulse of ~ -100 mV is required to completely activate the I_A current in the early myotube (Broadie and Bate, 1993d). Therefore, the prominent I_A current reported here is predicted to be completely nonfunctional under normal developmental conditions. As myogenesis proceeds, however, a developmental change can be observed, as the I_A steady-state inactivation curve develops a biphasic character (Broadie and Bate, 1993d). This change suggests that a low-voltage inactivation I_A channel is present early and replaced later by a high-voltage inactivation I_A channel. The I_A current at all developmental stages is completely eliminated in *Shaker* (Sh^{KS133}) mutants, suggesting that the Shaker I_A channel may be differentially regulated during development relative to the mature muscle (Broadie and Bate, 1993d). The mechanism and significance of this developmental shift in I_A channel properties remains unclear.

2.3.4.3. Development of Muscle Contractile Properties and Patterned Movement

The development of neuromuscular behavior in *Drosophila* has recently been quantitatively assayed using videomicroscopy to monitor peristaltic muscle contraction waves during the last quarter of embryogenesis, starting shortly after the completion of the muscle pattern and innervation through hatching (Suster and Bate, 2002). The muscle contractile machinery driving this movement closely resembles that of the vertebrate muscle: the basic contractile unit is the sarcomere, a Myosin thick filament surrounded by a regular array of Actin thin filaments (Zhang *et al*., 2000). Myosin and Actin are both expressed first in myoblasts during the process of fusion to form myotubes (~10 h at 25 °C; 40–50% development). If fusion is prevented, Myosin expression is clearly maintained in the unfused myoblasts (Rushton *et al*., 1995), indicating that the synthesis of contractile machinery is independent of myotube formation. Assembly of the contractile apparatus is a lengthy process, with the muscles first assembling recognizable sarcomeres at the end of stage 15 (~12.5 h at 25 °C; ~60% development). The first weak endogenous movements are observed at around 14–15 h (66–71% development), and electrical stimulation of the motor nerve first leads to a detectable muscle twitch during this same period (Broadie and Bate, 1993e). The embryo first begins to move vigorously during the period of 16–18 h (76–86% development), at which time clear body length peristaltic waves are first observed.

Embryonic movements include vigorous, repeated forward and backward waves of peristalsis (Suster and Bate, 2002). When NMJ neurotransmission is blocked with transgenic toxin expression or in a range of mutants (*syntaxin, synaptobrevin, dunc-13*), peristalsis is eliminated, indicating that it is completely dependent on neural input (Broadie *et al*., 1995; Sweeney *et al*., 1995; Aravamudan *et al*., 1999). In contrast, local body contraction of one or a few segments persists, as do quite vigorous head movements, driven by the myogenic activity of the pharyngeal muscles. Thus, embryonic peristalsis, similar to other repetitive movements, depends on central pattern generating (CPG) circuits that functionally mature during the last quarter of embryogenesis (Suster and Bate, 2002). Interestingly, removal of sensory inputs during development has shown that these are not essential for the differentiation of the CPG or maturation of behaviorally normal movement (Suster and Bate, 2002). By 18–19 h (85–90% development), the embryos seem

to have perfected larval locomotory movements. Within the egg shell, both forward and reverse locomotory movements are evident, involving coordinated waves of muscle contraction along all the body segments (Suster and Bate, 2002). Following this apparent entrainment period, the embryo becomes markedly inactive during the last few hours of embryogenesis. Quite abruptly, the hatching movement program is then engaged, initially involving vigorous head movements to puncture the egg shell and then forward peristaltic waves to drive the new larva free.

2.3.5. Development of NMJ Presynaptic Function

Once a motor neuron growth cone contacts an appropriate muscle target, the filopodia-ringed vacuolated sheet that characterizes the "seeking" axon terminus transforms itself into a branched presynaptic terminal with swellings (or "boutons") specialized for neurotransmitter release (Rheuben *et al*., 1999). Functional presynaptic terminals normally differentiate after contact with postsynaptic muscle, but the muscle targets do not need to be appropriate, or even present, for formation of relatively normal presynaptic structures (Prokop *et al*., 1996). In the grasshopper *Barrytettix*, for example, presynaptic terminals normally persist in adulthood opposite inappropriate targets, such as glia and basal lamina, after previously innervated nymph muscles degenerate (Arbas and Tolbert, 1986). Thus, presynaptic development, once triggered by unknown signals, appears to proceed to completion without any target derived signal. Without a differentiated postsynaptic target, however, presynaptic specializations are oriented randomly in the presynaptic membrane rather than exclusively toward the postsynaptic muscle target (Prokop *et al*., 1996). For example, *Drosophila twist* mutants do not form myoblasts (see above) and, thus, motor terminals are completely deprived of target cells. Nevertheless, fully differentiated presynaptic terminals form, except that presynaptic densities, with associated clusters of SVs, are oriented randomly. Fully formed but improperly oriented presynaptic specializations are also seen in *mef-2* mutants, which are capable of producing only undifferentiated myoblasts (see above; Prokop *et al*., 1996; Prokop, 1999). It is as if axons know "when" and approximately "where" to form a presynaptic terminal (presumably via regional cues during outgrowth) but, without interaction from a differentiated postsynaptic partner, they do not know exactly which way to point it.

As with other aspects of embryonic body wall development, differentiation of presynaptic nerve terminals occurs in a ventral to dorsal "wave," as axons growing outward from the ventral ganglion around the periphery of the cylindrical embryo meet increasingly distant and more dorsal muscles (Broadie *et al*., 1993; see **Figure 1**). This wave of development occurs throughout the latter half of embryogenesis, but differentiation of individual terminals occurs much more rapidly. In *Drosophila*, where embryogenesis lasts ~21 h at 25 °C, individual terminals mature from seeking growth cones to functional presynaptic structures in a few (2–3) hours (Broadie *et al*., 1993; Yoshihara *et al*., 1997). By the end of embryogenesis, each muscle is functionally innervated, but new boutons continue to be added, grow and differentiate throughout larval development.

2.3.5.1. Functional Development of the Presynaptic Terminal

The basic processes of presynaptic function appear to be highly conserved across phyla. Thus, insect nerve terminals are structurally and functionally very similar to those described in other animals, including the extensively described terminals of frog, mouse, and rat. Development of presynaptic function is difficult to track because neurotransmitter release is typically measured using activation of postsynaptic receptors as an assay. Nevertheless, all evidence suggests that at least some functional synaptic vesicle release machinery assembles prior to muscle target contact (Fletcher *et al*., 1994). For example, experiments in *Drosophila*, using voltage-clamped "sniffer cells" to detect neurotransmitter release from growing neuronal axons in culture, show that presynaptic terminals release neurotransmitters prior to contacting their postsynaptic target (Yao *et al*., 2000). Spontaneous and evoked activation of postsynaptic GluRs is also immediately detected after the nascent presynaptic terminal contacts target muscle, suggesting that presynaptic terminals are already functional before synaptogenesis *per se* (Broadie and Bate, 1993b, 1993e).

A more direct assay for presynaptic function is the uptake and release of lipophilic fluorescent dyes such as FM1-43, which stains and destains functional terminals during synaptic vesicle endocytosis and fusion, respectively (Cochilla *et al*., 1999). Chick growth cones in culture stain with FM1-43 (Diefenbach *et al*., 1999), but this dye uptake and release may be due to extensive membrane turnover caused by neurite growth and reorganization rather than synaptic vesicle cycling. *Drosophila* embryonic motor terminals also cycle FM1-43 efficiently

(Fergestad and Broadie, 2001), but their ability to do so prior to target contact has not been examined.

Other hallmarks of presynaptic differentiation include immunocytochemical detection of vesicle proteins such as Synaptotagmin, Synaptobrevin, and Cysteine string protein (CSP) (Parfitt *et al.*, 1995; Wu and Bellen, 1997), which appear as distinct puncta in differentiated presynaptic terminals (Featherstone *et al.*, 2001). Functionally mature synaptic terminals also concentrate neurotransmitters in their cytosol, a necessary prerequisite for pumping it up a steep concentration gradient into SVs. Glutamate immunoreactivity, localization of synaptic proteins such as Synaptotagmin, Synaptobrevin and CSP, clustered SVs, and presynaptic dense bodies (T-bars) are all visible in growth cones and during the earliest stages of presynaptic terminal differentiation, again supporting the idea that the presynaptic specializations are functional before target contact (Rheuben and Kammer, 1981; Broadie and Bate, 1993e; Broadie, 1996).

Spectrins are cytoskeletal membrane matrix proteins expressed ubiquitously in *Drosophila*, but concentrated at NMJs (Featherstone *et al.*, 2001). Spectrins are also prominent cytoskeletal components of mammalian synapses (Phillips *et al.*, 2001). Mutations that eliminate alpha and beta Spectrin in *Drosophila* show that both proteins are required for localization of most presynaptic proteins, including CSP, Synaptotagmin, Synapsin, and Syntaxin (Featherstone *et al.*, 2001), but neither nerve terminal morphology nor synaptic vesicle number or distribution are affected. Because of the mislocalization of presynaptic proteins, synaptic transmission is reduced to approximately 25% of normal. These results suggest that synaptic proteins are organized (probably indirectly) by a Spectrin scaffold during synaptogenesis.

2.3.5.2. Maturation of Neurotransmitter Release

In the NMJ of the *Drosophila* ventral longitudinal muscle 6/7, evoked EJCs increase from about 2000 pA in late-stage embryos to approximately 400 000 pA in third instar larvae, a 200-fold increase (Broadie and Bate, 1993e; Rohrbough *et al.*, 1999; Broadie, 2000). This increase is probably necessary in order to compensate for the large developmental drop in muscle input resistance (Lnenicka and Keshishian, 2000), which otherwise would lead to insufficient postsynaptic depolarization in larvae. This dramatic increase in synaptic efficacy could be accounted for by several factors: (1) an increase in the number of presynaptic boutons; (2) an increase in the number of active zones within each bouton; and/or (3) an increase in the number of postsynaptic GluRs (Featherstone *et al.*, 2002; Reiff *et al.*, 2002). The embryonic muscle 6/7 NMJs contain approximately 10 boutons. In third instar larvae, there are 50–100 boutons. Embryonic boutons typically contain 6–8 presynaptic active zones (Rheuben *et al.*, 1999), while third instar larvae boutons possess two to three times that number (Atwood *et al.*, 1993; Renger *et al.*, 2000). Therefore, the number of synapses (active zones) at each NMJ increases 10- to 30-fold over the course of late embryonic and larval development. Each active zone also increases in size, from about 200 nm in embryos (Prokop *et al.*, 1996; Prokop, 1999) to about 500 nm in third instar larvae (Atwood *et al.*, 1993; Rheuben *et al.*, 1999; Renger *et al.*, 2000). Consistent with this presynaptic change seen ultrastructurally, postsynaptic glutamate receptor clusters imaged confocally also increase in size approximately threefold between the end of embryogenesis and the end of third instar stage (D.E. Featherstone, unpublished data). In other words, embryonic through larval development of each NMJ involves all three changes mentioned above, i.e., addition of boutons, addition of active zones within each bouton, and an increase in size of each active zone. Nevertheless, these pre- and postsynaptic morphological differences account for only about half of the increase in EJC size measured during larval development. Thus during larval development, individual active zones also undergo functional changes that increase neurotransmitter release. Such changes could be due to increased presynaptic calcium channel influx (Yoshihara *et al.*, 2000; Reiff *et al.*, 2002), facilitated SNARE-mediated vesicle fusion, perhaps due to increased calcium sensitivity (Littleton *et al.*, 1993a, 1999), or more efficient vesicle cycling (Kuromi and Kidokoro, 1999).

Neurotransmitter release is highly dependent on extracellular calcium, which invades the presynaptic terminal when voltage-gated calcium channels open during presynaptic depolarization. Comparison of different electrophysiological studies suggests that the calcium dependence of NMJ neurotransmitter release approximately doubles between late embryos and third instar larva (Broadie, 1999). Thus, more release is achieved due to increased sensitivity to calcium. In *Drosophila*, the terminal membrane area increases many fold during development (from about 3 μm^2 in embryos to about 100 μm^2 in third instar larvae), potentially increasing the number of routes for calcium influx. Unfortunately, developmental studies of calcium channel density or calcium influx in terminals have not been performed. One explanation for the increased calcium sensitivity could be a developmental shift in the

expression of Synaptotagmin family members, which confer different calcium dependence to release (Littleton *et al.*, 1999). Several Synaptotagmin genes are indeed expressed in *Drosophila*, but a developmental shift in their expression at the NMJ has not yet been reported. From embryonic synaptogenesis through larval stages, each active zone also becomes associated with an increasing number of SVs. In the embryonic NMJs, for example, T-bars are typically surrounded by 5–10 vesicles, with few or no vesicles in the surrounding cytosol. In third instar larvae, T-bars are often surrounded by 2–3 dozen vesicles, with hundreds more in the nearby cytosol. The increased availability of SVs during development probably results in the fusion of more vesicles per stimulus at each active zone, as well as in fatigue resistance due to a larger number of reserve vesicles. Thus, the efficacy of individual active zones also increases during development, although the molecular mechanisms underlying these presynaptic changes remain largely unexplored.

2.3.5.3. Maturation of Mature Synaptic Properties

Early in synaptogenesis, when the motor nerve terminal first contacts the postsynaptic muscle (13.5 h; 60% embryonic development at 25 °C), endogenous currents at the nascent NMJ can be observed, although evoked transmission is easily fatigued and variable (Broadie and Bate, 1993e). Before 15 h of embryogenesis (68% development), when NMJs have just formed, the synapse fatigues rapidly and completely even with relatively low frequency (<5 Hz) stimulation (Broadie and Bate, 1993e). Between 16 and 18 h (72–82% development), NMJ transmission is more consistent, and patterned synaptic activity is observed such that higher stimulation frequencies (>5 Hz) are needed to induce fatigue, from which the terminal recovers within a few seconds (Broadie and Bate, 1993e). After 18 h, the NMJ maintains reliable transmission with little fatigue at stimulation frequencies up to about 10 Hz (Broadie and Bate, 1993e). Reliability and fatigue resistance increase throughout larval development. Thus, third instar *Drosophila* larvae are capable of maintaining transmission (albeit with marked depression) at very high stimulation frequencies (up to 50–100 Hz) with almost no failures (Rohrbough *et al.*, 1999; Featherstone, personal communications). These functional changes during development can be attributed again to several factors, including the addition of presynaptic boutons, the addition of active zones within those boutons, an increase in active zone size, an increase in functional efficacy of each active zone, and an enlargement of the postsynaptic receptor field.

Late-stage embryonic and larval NMJs also show increasing facility for activity-dependent synaptic plasticity, wherein synaptic properties change following specific patterns of stimulation (described in more detail in Sections 2.3.1.4 and 2.3.8). These changes may reflect maturation of intracellular signaling pathways and mechanisms for modulation (see discussion below).

2.3.5.4. Differentiation of Synaptic Vesicle Pools and Cycling

Most (>70%) SVs in embryonic motor terminals cluster around the active zone; relatively few vesicles are distributed throughout the center of the bouton, despite the large amount of space available (Prokop *et al.*, 1996; Prokop, 1999). In larval terminals, however, bouton centers are often filled with vesicles, and vesicles are stacked many rows deep around active zones (Atwood *et al.*, 1993; Rheuben *et al.*, 1999; Renger *et al.*, 2000). Electron microscopy, in combination with electrophysiological and mutant analyses, has shown that the vesicles immediately adjacent to active zones are sufficient for basal neuromuscular transmission. Furthermore, ultrastructural and dye studies suggest that, typically, only a minority of presynaptic vesicles are usually involved in basal transmission. Locust terminals, for example, only show, on average, a 20% decrease in vesicle density after stimulation (Titmus, 1981). In *Drosophila*, high bath potassium, which depolarizes cells and triggers release, causes release of about half of the total number of SVs (Kuromi and Kidokoro, 1998).

Only under very high frequency stimulation or, especially, in conditions where endocytosis is inhibited, are the majority of vesicles recruited (Kuromi and Kidokoro, 1998, 1999, 2000, 2002). These reluctantly recruited "reserve" vesicles are the morphologically "central" vesicles not associated with active zones. Under conditions of high vesicle demand, such as high-frequency stimulation or impaired endocytosis, these reserve vesicles supplement and/or replace vesicles from the primary pool. In embryos, the reserve pool is absent – there are only vesicles immediately around T-bars, and the centers of boutons are devoid of SVs. Consistent with this, embryos display markedly lower fatigue resistance (Broadie and Bate, 1993e), because they have no reserve vesicle pool (Prokop, 1999; Fergestad and Broadie, 2001). Because embryos only contain vesicles around their T-bars, we can also infer that nascent vesicles, which all embryos have, are first targeted to active zones and, when these areas are sufficiently occupied, a reserve pool begins to develop. In mutant larvae that develop without

Endocytosis (e.g., *Drosophila* Endophilin mutants), the cycling pool is greatly reduced and the reserve pool is completely absent (Verstreken *et al*., 2002), again arguing that vesicles are first targeted to active zones and then, as this area fills, to the "reserve pool." Because Cytochalasin D, a selective disruptor of filamentous Actin, eliminates the reserve pool, it is thought that actin is responsible for incorporating or maintaining SVs in the reserve pool (Kuromi and Kidokoro, 1998). CyclicAMP signaling mutations also disrupt reserve vesicle recruitment (Kuromi and Kidokoro, 2000), demonstrating a need for this pathway in building and/or maintaining the reserve vesicle pool. In *Drosophila*, cAMP levels are increased by cytosolic calcium (Kuromi and Kidokoro, 2002), suggesting that calcium probably regulates vesicle pool size in insects as it does in mammals.

Taken together, these observations suggest that the increased fatigue resistance seen in late larval NMJs, compared to embryonic NMJs, is due to gradual accumulation of a reserve vesicle pool, which forms after the primary vesicle pool.

2.3.6. Development of NMJ Postsynaptic Function

2.3.6.1. The Muscle Membrane Prior to Innervation

Prior to innervation, the *Drosophila* body wall muscle membranes express cell adhesion molecules (CAMs) such as FasIII, FasII, Connectin, and Toll, which appear to mediate motor axon guidance and/or target recognition. FasII and Connectin are initially expressed throughout the muscle membrane, but are localized to NMJs during the initial stages of NMJ formation. FasIII, on the other hand, is initially loosely localized only near the normal site of muscle innervation, as if to mark the site, and then disappears after the start of NMJ development. Consistent with the idea that these CAMs mediate cell–cell "stickiness," overexpression of FasII results in ectopic synapses due to "trapping" of growth cones that normally explore several potential targets before selecting the proper postsynaptic cell. Similarly, misexpression of FasIII causes inappropriate synapses between axons that normally innervate FasIII-expressing muscles and the muscles that misexpress FasIII (Chiba *et al*., 1995; Suzuki *et al*., 2000). Toll, on the other hand, is repulsive to neurons that do not ordinarily innervate Toll-expressing muscles (Rose *et al*., 1997; Suzuki *et al*., 2000). Since each motor neuron innervates a unique muscle (or set of muscles), there is presumably a unique molecular cell adhesion "code" that allows matching between appropriate pre- and postsynaptic partners (Chiba and Rose, 1998). The CAM interactions between undecided partners are apparently aided by mobile cellular protuberances on both the pre-(growth cone filopodia) and postsynaptic sides. Decades ago, it was observed that the embryonic insect muscle appears "ruffled" at the normal site of innervation (Walther, 1981). Close examination has revealed that the membrane ruffling is due to small muscle membrane projections reminiscent of the axonal growth cone filopodia. These projections, termed "myopodia," are extended randomly from the muscle surface before innervation, but cluster at the site of innervation during contact by the appropriate motor neuron growth cone (Ritzenthaler and Chiba, 2003).

Fast excitatory signaling at insect NMJs occurs via postsynaptic ionotropic GluRs (Usherwood, 1977). In *Drosophila* NMJs prior to innervation, functional receptors are scattered in small numbers throughout the postsynaptic muscle membrane, such that iontophoresis of glutamate opens only one or two channels regardless of application site (Broadie and Bate, 1993b). Discs Large (Dlg) is the *Drosophila* homolog of mammalian PSD-95, a MAGUK (membrane-associated guanylate kinase) protein that is prominent at glutamatergic synapses. Similar to GluRs, Dlg is diffusely expressed initially, but localized and upregulated at synapses after innervation (Thomas *et al*., 2000).

2.3.6.2. Development of Postsynaptic Glutamate Receptors

Once the proper axon and muscle contact each other, they form a functional, albeit weak, synapse within minutes (Broadie and Bate, 1993b, 1993e). Consistent with this, postsynaptic glutamate receptors are distributed at low levels throughout the muscle membrane prior to innervation. Under normal circumstances, receptors outside the area of muscle contact disappear within an hour, while the number of synaptic receptors simultaneously increases (Broadie and Bate, 1993b; Saitoe *et al*., 1997), presumably as preexisting receptors cluster at the site of innervation (however, the possibility that new synaptic receptors are inserted while extrasynaptic receptors are degraded, has not been excluded). In *Drosophila*, EJCs, measured from barely innervated ventral muscle 6 at 13.5 h (60% of embryonic development), increase from single channel size (about 12 pA at −60 mV) to approximately 700 pA by 15 h (68% development). After this initial phase of postsynaptic development, EJC size gradually triples (to about 2000 pA) by the end of embryogenesis (22 h) (Broadie and Bate, 1993b),

as new receptors are synthesized and inserted. Glutamate receptor upregulation in *Drosophila* fails if presynaptic electrical activity is completely blocked using either Tetrodotoxin (TTX) or genetic ablation of voltage-gated sodium channels (Broadie and Bate, 1993a; Saitoe *et al*., 1997). Incomplete blockage or increased activity have relatively minor effects on postsynaptic development (Broadie and Bate, 1993a) (see **Figure 4**).

Without innervation, GluRs are neither localized nor upregulated (Broadie and Bate, 1993b). Furthermore, clustering and upregulation of receptors occurs at ectopic synapses. Thus, contact by the presynaptic nerve terminal is both necessary and

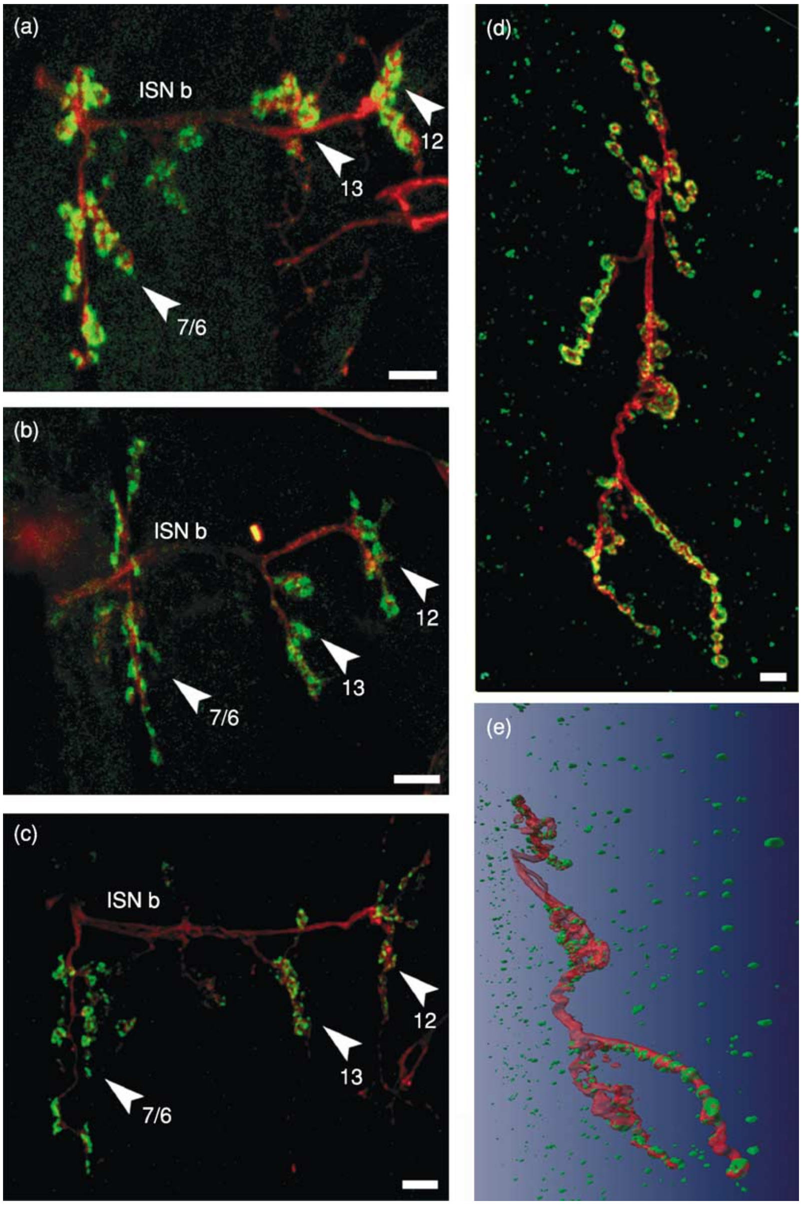

Figure 4 Confocal micrographs showing the development of *Drosophila* ventral longitudinal embryonic/larval NMJs, visualized using antibodies that recognize neuronal tissue (HRP, red) and glutamate receptor subunit GluRIIA (green). (a–c) Motor axons from the intersegmental nerve (ISNb) branch b form NMJs on ventral longitudinal muscles 7, 6, 13, and 12, in very late-stage (22 h, 100% embryonic development) embryos (a), first instar larvae (b), and second instar larvae (c). (d) The 6/7 NMJ in a third instar larva. Scale bar: 10 μm in all panels. Note the slight change in scale bar length between images. Over development, NMJ arbors grow larger and branchier, and glutamate receptor cluster size increases about threefold in area. Note also the large number of extrasynaptic glutamate receptor clusters visible in third instar muscle (d). Panel (e) shows a three-dimensional isosurface rendering of the same NMJ presented in panel (d), rotated slightly to show the edge of the confocal section visible near the upper left, where the axons extend to meet the bottom side of the muscles (which is the side facing away from the interior of the larvae).

sufficient for postsynaptic development. Similar to GluRs, Dlg is diffusely expressed initially, but localized and upregulated at synapses after innervation (Thomas *et al*., 2000). Like GluRs, Dlg is neither synaptically localized nor upregulated in the absence of innervation (D.E. Featherstone, unpublished data). The signal from nerve to muscle that triggers postsynaptic development, however, is unknown. In mammalian NMJs, the secreted proteoglycan Agrin triggers receptor clustering and upregulation of postsynaptic ACh receptors via a muscle specific receptor tyrosine kinase (MuSK) (Sanes and Lichtman, 1999). Glutamatergic synapses, including insect NMJs, however, appear to use a different signal for postsynaptic induction (Colledge and Froehner, 1998). No obvious Agrin homolog is encoded by the *Drosophila* genome, and several kinases similar to MuSK, such as Neurospecific receptor kinase (Nrk), Heartless (Htl), and RAR-related orphan receptor (Ror), appear to be expressed in neurons (where Ach receptors are expressed), but not muscle. The Wnt protein encoded by the *wg* gene has recently been shown to concentrate in developing larval NMJs, where it appears to be secreted by the presynaptic terminal. In *wg* mutants, or larvae with mutations in the TGF β type II receptor encoded by the gene *wishful thinking* (*wit*), NMJs remain underdeveloped (Packard *et al*., 2002). Thus, Wg signaling via Wit has been proposed to be an essential intercellular signal necessary for coordination of pre- and postsynaptic differentiation (Packard *et al*., 2003).

Wnts are known to participate in many other cell–cell interactions during development, and have been implicated in presynaptic differentiation in mammalian synapses (Salinas, 1999). However, although Wnt signaling appears to regulate larval NMJ development, it does not seem to be required for synaptogenesis, and it remains to be established whether Wnts are secreted by insect motor neuron growth cones prior to target contact (which would be required for the initial induction signal). The Spectrin cytoskeleton is required for proper localization of Dlg but not glutamate receptors (Featherstone *et al*., 2001), suggesting that although clustering and upregulation of both these postsynaptic proteins depends on a nerve-derived signal, the mechanisms by which they localize diverge thereafter.

Postsynaptic glutamate receptor (GluR) mRNA is translated at NMJs and the translation initiation factor eIF4E as well as the poly(A)-binding protein PABP, which are required for translation, are localized in the postsynaptic muscle near NMJs. Their genetic disruption alters synaptic development and GluR function (Sigrist *et al*., 2000). Consistent with local translation, Sigrist *et al*. (2000) also showed that GluR mRNA is localized near NMJs. This result, however, differs from earlier examinations which showed that GluR mRNA is widely distributed in embryonic and larval muscle fibers (Currie *et al*., 1995). Induction of GluR fields by the presynaptic nerve could trigger transcription of GluR mRNA, local translation of pre-existing mRNAs, or both. Preliminary evidence (Q. Sheng and D.E. Featherstone, unpublished data) suggests that innervation dependent upregulation of glutamate receptors during embryogenesis does not involve transcription, since mRNA levels remain unchanged while receptor protein accumulates.

Once induced, postsynaptic GluRs in *Drosophila* form distinct clusters under presynaptic terminals (Featherstone *et al*., 2002). Between late embryogenesis and third instar larval stage, the GluR cluster size area increases threefold (from about 0.5 μm^2 to about 1.5 μm^2; D.E. Featherstone, unpublished data). This size increase matches almost perfectly the postsynaptic density diameter measured by electron microscopy (Rheuben *et al*., 1999) and the increases in miniature junction currents recorded electrophysiologically (which increase from about 150 pA in embryos to 500 pA in third instars) (Rohrbough *et al*., 1999; Featherstone and Broadie, 2000; Featherstone *et al*., 2001). Because changes in the receptor cluster area mirror the functional (mEJC size) alterations so closely, receptor density within each cluster probably does not change during development. The number of receptor clusters per bouton also does not increase dramatically during larval development, but the bouton number does; therefore, the number of clusters at each NMJ also increases.

In addition to synaptic GluRs, extrajunctional GluRs have been found electrophysiologically and microscopically in the muscle membrane of all insects examined (Cull-Candy, 1976; Usherwood, 1994; Nishikawa and Kidokoro, 1995). There are two types of extrajunctional GluRs: D and H, which, when activated, depolarize and hyperpolarize the muscle membrane, respectively (Cull-Candy, 1976). The H receptor current appears to be carried by Avermectin-sensitive glutamate-gated chloride channels (Cully *et al*., 1996) and may be specific to adult muscle (Saito and Kawai, 1985). Excitatory D receptors are expressed during larval development, but the function of these nonsynaptic receptors is not understood. One hypothesis is that these extrajunctional D receptors represent "synaptic" receptors moving to/from the postsynaptic density. This is thought to be the case in embryonic muscle, where the disappearance of extrajunctional

receptors immediately following innervation is coincident with the appearance of junctional receptors (Broadie and Bate, 1993a; Saitoe *et al*., 1997). As the postembryonic muscle matures, however, extrajunctional receptors return to prominence (in *Drosophila*, during second instar stage; see **Figure 4**).

Extrajunctional receptors differ from junctional receptors in fundamental functional ways (Usherwood, 1994; Nishikawa and Kidokoro, 1995). For example, extrajunctional receptors have lower conductance, less rectification, and decreased calcium permeability compared to junctional ones (Usherwood, 1994; Nishikawa and Kidokoro, 1995). In the *Drosophila* muscle, this permeability difference is large enough to shift the receptor current reversal potential from near zero (for extrajunctional receptors) to positive (about 12 mV) values (Nishikawa and Kidokoro, 1995). Extrajunctional receptors also desensitize much more rapidly (in ~15 ms; Heckmann and Dudel, 1997) compared to junctional receptors (Nishikawa and Kidokoro, 1995). If extrajunctional receptors represent a pool of synaptic receptors held in "reserve" or trafficked to/from the synapse, then the differences in functional properties must represent a form of regulation determined by differential localization.

Although GABA-gated currents have also been demonstrated in some insect muscle (typically adult muscle), they are not present in the *Drosophila* embryonic/larval body wall muscle (Broadie, 1999; Featherstone and Broadie, 2000). Glutamic acid decarboxylase (GAD), the enzyme responsible for synthesizing the neurotransmitter GABA is, however, expressed in embryonic and larval motor nerve terminals, where it regulates cytosolic glutamate levels and (indirectly) postsynaptic GluR numbers (see Section 2.3.6.3). The presence of GAD protein in embryonic/larval motor neurons without apparent GABAergic transmission may also suggest that these motor neurons become GABAergic during metamorphosis. However, this possibility has not been investigated and no circumstantial evidence exists for it. Essentially nothing is known about the development of GABAergic transmission in insects, including whether insect GABA receptors are localized using mechanisms similar to those employed by vertebrates (Kardos, 1999; Sassoe-Pognetto and Fritschy, 2000; Fritschy and Brunig, 2003). The *Drosophila* protein Cinnamon (Cin), previously identified as a molybdenum cofactor, represents a fly homolog of Gephyrin, which is a mammalian protein important for glycine and GABA receptor field development (Kamdar *et al*., 1994; Wittle *et al*., 1999). Cinnamon's role in insect synaptic development or inhibitory neurotransmission has not yet been explored.

2.3.6.3. Molecular Maturation of Postsynaptic Signaling

As mentioned earlier, *Drosophila* third instar larval muscles contain large aggregates of the translation initiation factors eIF4E and poly(A)-binding protein (PABP) in or near the SSR of NMJs (Sigrist *et al*., 2000). According to Sigrist *et al*. (2000), GluR mRNA is localized near these postsynaptic translation aggregates (but others claim that GluR mRNA is unlocalized; Currie *et al*., 1995). When synaptic activity or cAMP levels are upregulated using K^+ channel (*eag,sh*) or cAMP-phosphodiesterase (*dunce*) mutants, respectively, the number of postsynaptic translation aggregates increases, the amount of postsynaptic glutamate receptors goes up (without a corresponding rise in mRNA), and EJC size increases (Sigrist *et al*., 2000). Increased larval locomotion also upregulates the number of postsynaptic translation aggregates and receptors (Sigrist *et al*., 2003). These activity-dependent changes can be rapidly reversed by using a temperature sensitive mutation in a voltage-gated sodium channel to induce paralysis and thus decrease NMJ activity (Sigrist *et al*., 2003). Taken together, these data suggest that *Drosophila* NMJ glutamate receptors are synthesized in or near the SSR by translation factors that are somehow regulated by synaptic activity. Postsynaptic synthesis probably allows faster synaptic changes; indeed, Sigrist *et al*. (2003) measured significant changes in synaptic strength after 2 h.

Synthesis and insertion of new receptors is not the only mechanism by which *Drosophila* NMJs control glutamate receptor number. The number of NMJ postsynaptic glutamate receptors at any time after initial induction represents a balance between receptor addition and receptor downregulation. In *Drosophila*, the presynaptic neuron slows the addition of postsynaptic receptors by secreting a signal that triggers receptor downregulation. Surprisingly, this signal is glutamate itself, released via an as yet unknown nonvesicular mechanism. In a genetic screen for mutations that affect postsynaptic development, Featherstone *et al*. (2000) paradoxically discovered that GAD enzyme levels in glutamatergic terminals regulate the number of postsynaptic glutamate receptors. Since *Drosophila* embryonic/larval NMJs are not GABAergic (Jan and Jan, 1976a; Broadie and Bate, 1993e; Featherstone *et al*., 2000), it was hypothesized that GAD's primary function in the NMJ was to degrade glutamate, and that glutamate caused downregulation of its postsynaptic receptors. By genetically manipulating the concentration of presynaptic cytosolic glutamate,

Featherstone *et al.* (2002) showed that the number of postsynaptic glutamate receptors is inversely correlated with presynaptic glutamate levels, consistent with the hypothesis that extracellular glutamate released from presynaptic nerve terminals causes downregulation of postsynaptic glutamate receptors. Thus, the nerve terminal first induces the clustering and upregulation of glutamate receptors (see Section 2.3.6.2), and then gradually puts a brake on the process using glutamate. Interestingly, glutamate-triggered downregulation of glutamate receptors is not blocked by mutations that eliminate synaptic vesicle fusion (Broadie *et al.*, 1995; Sweeney *et al.*, 1995; Aravamudan *et al.*, 1999; Featherstone *et al.*, 2002), demonstrating that glutamate-triggered receptor downregulation is primarily mediated by nonvesicular glutamate.

Even after excitatory glutamatergic transmission at insect NMJs was widely accepted, mammalian physiologists were still questioning whether glutamate could serve as a transmitter in the vertebrate CNS (Nicholls and Sihra, 1986). One of the main arguments against glutamate was the fact that extracellular glutamate levels in the vertebrate nervous system seemed too high. Extracellular glutamate also triggers downregulation of glutamate receptors in cultured mammalian neurons (Lissin *et al.*, 1999), and nonvesicular neurotransmitter release through various antiporters, neurotransmitter pumps, gap junctions and other channels, has recently been demonstrated in mammalian cells (Attwell *et al.*, 1993; Baker *et al.*, 2002; Demarque *et al.*, 2002; Duan *et al.*, 2003; Ye *et al.*, 2003). Regulation of glutamate receptors by nonvesicular glutamate may thus be a conserved mechanism by which presynaptic terminals balance presynaptic properties and postsynaptic sensitivity. However, the mechanisms by which nonvesicular glutamate is released and the methods that the muscle cell uses for receptor downregulation remain to be elucidated. It also remains unknown whether receptors containing specific subunits are preferentially downregulated, so that receptor properties are "tuned" depending on innervation.

2.3.7. Postembryonic Maturation of the NMJ

Although a functional NMJ is fully established (e.g., functional pre- and postsynaptic elements are in place) by the end of embryogenesis, the synapse continues to grow and elaborate dramatically during the larval stages (Walther, 1981). Almost none of this postembryonic development occurs without extensive input from the synaptic partner, and all of it appears to be regulated by complex and incompletely described cascades of intracellular messengers.

2.3.7.1. Elaboration of Synaptic Architecture

Between hatching and late larval stages, the size and structural elaboration of NMJs increase dramatically. New synaptic boutons and axonal branches are added to make, in general, a larger, "bushier" presynaptic arbor. Time-lapse studies suggest that there is no specific growth zone for presynaptic elaboration (Zito *et al.*, 1999). Rather, new terminals or branches are added, apparently randomly, either by splitting of pre-established boutons, the formation of new boutons on pre-established branches, or bouton formation at the end of terminal branches (Zito *et al.*, 1999). NMJ growth and subsequent morphology depends strongly on synaptic activity. As described above (see Section 2.3.6.3), NMJ locomotory activity in larvae induces accumulation of postsynaptic translation aggregates, increased production of postsynaptic glutamate receptors, and increased EJC size within 2 h. On a longer time scale (12–24 h), increased NMJ activity also induces dramatic synaptic growth (Budnik *et al.*, 1990; Sigrist *et al.*, 2000; Sigrist *et al.*, 2003). How are NMJ activity and morphology linked? Increased activity, as well as genetic manipulation of cAMP levels, are associated with a large (~50%) reduction in pre- and postsynaptic FasII at the NMJ and increased NMJ size (Davis *et al.*, 1996b; Schuster *et al.*, 1996b; Cheung *et al.*, 1999; Sigrist *et al.*, 2000, 2003). Reductions in FasII are both necessary and sufficient for NMJ growth (Schuster *et al.*, 1996b), but neither the FasII level changes nor the subsequent alterations in NMJ size affect synaptic function (Davis *et al.*, 1996b). Activity-dependent changes in synaptic function associated with NMJ growth require cAMP signaling via the cAMP response element binding protein CREB (Davis *et al.*, 1996b), in addition to the faster changes in glutamate receptor synthesis described above (see Section 2.3.6.3). Thus, NMJ activity induces cAMP levels and FasII downregulation, which upregulate synaptic function and growth, respectively. FasII levels may also be coupled to synaptic activity via presynaptic calcium released from intra- or extracellular stores, and triggered perhaps by phospholipase C activation, since changes in these processes also affect synaptic growth (Hannan and Zhong, 1999).

Because FasII is a cell adhesion molecule, it was suggested that synaptic growth is regulated by a careful balance between adhesion (which makes the neuron "grip" the muscle) and repulsion (which allows the neuron to grow over the muscle surface). Consistent with this, integrins are also expressed at

NMJs and required for normal morphology and function of *Drosophila* NMJs (Beumer *et al.*, 1999, 2002; Rohrbough *et al.*, 2000). Beta PS integrins appear to act through CamKII to regulate Dlg and FasII (Beumer *et al.*, 2002). Dlg is itself regulated by CamKII and required for FasII localization and NMJ growth (Budnik *et al.*, 1996; Thomas *et al.*, 1997; Koh *et al.*, 1999).

In addition to a careful balance in cell adhesion, NMJ growth also depends on the microtubule cytoskeleton and control of its assembly (Hummel *et al.*, 2000; Roos *et al.*, 2000; Zhang *et al.*, 2001; Eaton *et al.*, 2002; Pennetta *et al.*, 2002). *Drosophila* NMJ boutons contain microtubule loops oriented parallel to the postsynaptic muscle membrane (Roos *et al.*, 2000). During formation of new boutons, these cytoskeletal loops are rearranged. The *Drosophila* Futsch protein is a MAP1B homolog required for the microtubule rearrangements and thus for new bouton formation (Roos *et al.*, 2000). Futsch protein levels are controlled by the fragile X related protein (FXR), a mRNA binding protein and translational repressor (Zhang *et al.*, 2001). In *fxr* mutants, Futsch levels are increased and NMJs are overgrown, similar to the synaptic overgrowth found in human victims of fragile X mental retardation (Zhang *et al.*, 2001).

2.3.7.2. Formation of the SSR

During *Drosophila* embryogenesis, there is no SSR at the NMJ. At about the time of hatching, postsynaptic muscle cells produce short arm-like membrane extensions around type I presynaptic terminals, which also begin to sink into a growing dip in the postsynaptic membrane. By late larval stages, the presynaptic type I terminal is typically buried within layers of elaborately infolded muscle membrane (Rheuben *et al.*, 1999). The SSR forms in only a subset of NMJs. Specifically, it is most elaborate in type Ib, smaller in type Is, and undetectable in types II and III boutons (Lane, 1985; Rheuben *et al.*, 1999). Presumably, type I terminals possess a specific secreted or transmembrane "tag" that allows muscles to recognize them as such and build an SSR. No candidates for this presynaptic tag have been proposed. On the postsynaptic side, however, it has been shown that Dlg is critical for SSR formation (Lahey *et al.*, 1994; Budnik *et al.*, 1996; Guan *et al.*, 1996).

The insect SSR, like the membrane folds at mammalian NMJs, is thought to allow a higher density of membrane proteins in the region of the presynaptic terminal. The SSR may also be important for control of the fluid microenvironment around the NMJ, since insects have been shown to maintain fluid compositions around their nervous system that are dramatically different from the composition found elsewhere in the relatively open blood system (Treherne, 1985; see also Section 2.3.3). When the SSR is insufficiently developed due to mutations that affect levels of Dlg, the number of postsynaptic glutamate receptors is also decreased (Parnas *et al.*, 2001). This change is probably due simply to a reduction in available postsynaptic membrane, since loss of Dlg does not affect glutamate receptor numbers or localization prior to formation of the SSR (D.E. Featherstone, unpublished data).

2.3.7.3. Developmental "Feedback" between Pre- and Postsynaptic Cells

After initial synapse formation, the morphology and function of NMJs continue to change during larval development. Typically, postsynaptic muscle volume increases several tenfold, and presynaptic arbor area increases several fold. To maintain coordinated movement, it is important that muscle depolarization following nerve activity remain relatively invariant throughout this dramatic growth. To ensure this, presynaptic neurotransmitter release is developmentally regulated based on levels of postsynaptic depolarization. For example, *Drosophila* mutants with decreased muscle depolarization (due to manipulation of voltage-gated potassium channels or glutamate receptors in the muscle) develop larval presynaptic terminals with double the normal number of T-bars and more neurotransmitter release (Haghighi *et al.*, 2003). This increase in neurotransmitter release increases transmission "throughput" and corrects the deficit in muscle depolarization. Because the apparent "goal" of these changes is to maintain the size of the postsynaptic depolarization, the term "synaptic homeostasis" has been used (Paradis *et al.*, 2001). Although the retrograde (muscle to neuron) signal that mediates synaptic homeostasis remains unidentified, CamKII is required postsynaptically (presumably to "sense" depolarization levels), and a bone morphogenetic protein (BMP) type II receptor is required presynaptically (presumably to receive the retrograde signal) (Haghighi *et al.*, 2003). Alterations in glutamate receptor number do not cause compensatory changes in embryonic NMJs, suggesting that homeostatic changes occur during larval development (Broadie and Bate, 1993a; Featherstone *et al.*, 2000, 2002).

Paradoxically, manipulations that increase postsynaptic glutamate receptor numbers in larvae (such as overexpression of the receptors themselves, overexpression of postsynaptic translation aggregate proteins, or increased NMJ activity; Sigrist *et al.*, 2000, 2002, 2003) increase the density of

presynaptic active zones and number of boutons (Sigrist *et al*., 2002). Synaptic homeostasis predicts that more receptors would cause a reduction of NMJ size, as the presynaptic cell tries to compensate for increased postsynaptic sensitivity.

2.3.8. Development of Activity-Dependent Synaptic Plasticity

2.3.8.1. Development of Activity-Dependent Functional Plasticity

Two types of developmental plasticity have been recognized at the *Drosophila* NMJ: "morphological plasticity" and "functional plasticity." Morphological plasticity involves changes in NMJ size (bouton number, terminal length, or branching), which may or may not alter the size of postsynaptic currents. Functional plasticity involves changes in the size of postsynaptic EJCs, which may or may not involve alterations in NMJ size. As described in previous sections, NMJ activity levels can have dramatic effects on both NMJ growth (morphological plasticity) and EJC size (functional plasticity). Because morphological changes typically take a relatively long time (many hours in *Drosophila*) to manifest, activity-dependent morphological plasticity is usually assayed in third instar NMJs following chronic genetic manipulations. Activity-dependent functional plasticity, however, can be observed following both chronic (days) and acute (milliseconds–minutes) manipulations. The latter type of functional plasticity is considered "short-term functional plasticity." As described in Section 2.3.1.4, several types of short-term functional plasticity can be observed in *Drosophila* NMJs: (1) paired-pulse facilitation (PPF); (2) short-term facilitation (STF); (3) augmentation; and (4) posttetanic potentiation (PTP). All forms of short-term plasticity first develop late in embryogenesis (Broadie *et al*., 1997), but are much more robust and reproducible in third instar larvae (Zhong *et al*., 1992; Rohrbough *et al*., 2000). Mutations that affect learning and memory also affect short-term plasticity in the fly NMJ, suggesting that learning and memory utilizes processes shared by very different synapses. Proteins shown to be required for both learning and memory and NMJ plasticity in *Drosophila* include integrins (Rohrbough *et al*., 2000), 14-3-3 proteins (Broadie *et al*., 1997), and molecules involved in cAMP signaling (Zhong *et al*., 1992). Frequenin is a novel *Drosophila* neuronal synaptic calcium binding protein that facilitates frequency dependent facilitation in NMJs (Pongs *et al*., 1993). The mammalian homolog of Frequenin, called Neuronal calcium sensor-1 (NCS-1), has been shown to be both necessary and sufficient for paired pulse facilitation in glutamatergic synapses (Sippy *et al*., 2003). Plasticity might improve during larval development as signaling pathways mature (e.g., proteins like Frequenin accumulate at the synapse), or the variable and easily fatigued nature of transmission at younger stages might just make activity-dependent plasticity more difficult to trigger and measure.

2.3.9. Distant Signals: Hormonal Effects on NMJ Development and Function

The embryonic/larval insect PNS and body wall musculature is, as in most invertebrates, bathed by a relatively open circulatory system. Thus, the NMJ is readily accessible to any of the many substances produced by neurosecretory cells throughout the animal. Any bioactive substance transported from relatively distant cells is a hormone, but since synaptic transmission is really a short-distance form of endocrine signaling specialized for speed and specificity, the difference between presynaptic effects and hormonal effects can degenerate into semantics. For example, in addition to motor inputs utilizing "fast" neurotransmitters (e.g., glutamate or GABA), the larval body wall musculature also contains terminals that secrete peptides and amines such as PACAP, Proctolin, Leucokinin, Insulin, and Octopamine (Lane, 1985; Hannan and Zhong, 1999). There are receptors for some of these substances on neighboring muscle, but active zones for these "modulatory" terminals are often oriented away from the muscle, toward the body cavity (Lane, 1985; Orchard and Loughton, 1985; Prokop, 1999). Thus, although the target(s) of these substances may include muscle cells immediately adjacent to the terminal, distant muscle cells and other tissues may also be affected (Orchard and Loughton, 1985). As a result, the peptides and amines could be considered both as transmitters and hormones. The literature covering insect endocrinology is extensive, since almost every aspect of postembryonic insect development is regulated by hormones. Here, just a very few examples of how hormones affect NMJ growth and function are considered.

2.3.9.1. Evidence for Hormonal Regulation of NMJ Development

Almost all aspects of insect postembryonic development depend strongly on hormones. Development of the NMJ is no exception. Ecdysone is a hormone predominantly associated with developmental

changes during metamorphosis, which peaks in concentration during late larval stages just prior to pupation **Chapters 2.4**, **3.3**, **3.5**, and **3.10**). In *Drosophila* mutants where ecdysone is eliminated, the strength of NMJ transmission in the early third instar larva is unchanged, but is increased slightly (~20%) in the late third instar larva (Li and Cooper, 2001). Consistent with this, late (but not early) third instar ecdysoneless mutants also show NMJs with longer branches and more synaptic boutons (Li and Cooper, 2001). Thus, ecdysone appears to slow larval NMJ growth prior to pupation.

Calcium activated protein for secretion (CAPS) is a highly conserved protein that is required for fusion of dense cored vesicles containing neuropeptides and appears to be necessary for release of all peptide hormones. Genetic elimination of CAPS (and thus all peptide hormone secretion) in *Drosophila* results in reduced movement and embryonic/early larval lethality. Mutant embryonic NMJs have transmission strength reduced to approximately one-half the normal, with no obvious changes in synaptic morphology. Selective expression of CAPS only in presynaptic neurons does not correct the NMJ defects, demonstrating that the reduction in transmission is entirely due to loss of one or more (unidentified) peptide hormones originating in other cells (Renden *et al*., 2001). It is possible that, were CAPS mutants to live beyond the early first instar stage, more dramatic effects on NMJ development and function might be observed due to loss of peptidergic output. The specific neuropeptides(s) responsible for deficient NMJ development in *dCAPS* mutants remains unidentified.

2.3.9.2. Modulation: Short-Term Hormonal Regulation of NMJ Function

Many hormones have dramatic effects on behavior and several studies have demonstrated short-term modulation of NMJ function in larvae. This modulation can result in increases or decreases in NMJ transmission. For example, the mysosuppressing FLRFamide has been identified in the nervous systems of many insect species, including moths, cockroaches, locusts, flesh flies, and fruit flies (Nachman *et al*., 1996). Myosuppressins cause potent inhibition of muscle contraction. Direct application of FLRF or analogs to the mealworm NMJ results in reduced synaptic transmission, suggesting that one of the normal targets of myosuppressins is the NMJ (Nachman *et al*., 1996). FLRFamide analogs also affect other insect synapses (Nachman *et al*., 1996). FMRFamides are another class of neuropeptides found in many insect species. FMRFamide-related peptides increase larval muscle contraction. Like FLRFamide, the target of FMRFamide is the NMJ. Direct application of 0.1 μM FMRFamide in *Drosophila* increases postsynaptic currents to approximately 150% of normal (Hewes *et al*., 1998). Presumably, any hormone that constitutively affects NMJ function will eventually trigger activity-dependent developmental changes such as homeostatic upregulation of transmitter release or alterations in synapse morphology.

2.3.10. Unanswered Questions

The purpose of this chapter is twofold: (1) to summarize the current state of knowledge about functional neuromuscular development in insects (especially *Drosophila*); and (2) to highlight some of the many remaining havens of ignorance concerning this topic. Our focus here has been largely restricted to *Drosophila*, as it is almost exclusively in fruit flies that the genetic and molecular bases of neuromuscular development have begun to be dissected. Despite the rapid and remarkable progress made recently using flies, many questions remain regarding insect neuromuscular development and functional maturation of synapses. The following list of unanswered questions is, of course, not exhaustive. Rather, it highlights areas that, in our opinion, represent the highest priorities for investigation.

First, there is a general deficit in truly *developmental* studies. *Drosophila* mutant screens designed to study NMJ proteins usually try to isolate either conditional (i.e., temperature sensitive) mutants, or morphological mutants. Conditional mutant screens intentionally seek to avoid "developmental artifacts." Morphological mutants infer developmental problems, but the progression of the phenotype (which is typically measured in third instar larvae just prior to pupation) during NMJ development is almost never explored. Thus, we are typically left knowing that something at some time went wrong, but we do not know exactly what or when or where. This is inadequate.

Drosophila neurobiologists have been baffled by the difficulty of perturbing motor neuron–muscle connectivity with traditional loss-of-function mutants. Mutations in most genes with accepted roles in axon outgrowth and target recognition typically display relatively low penetrance (e.g., the phenotypes are spotty). Low penetrance is typically blamed on redundancy, where each pair of pre- and postsynaptic targets recognizes each other using multiple cues. Redundancy seems to be required by the fact that motor neuron growth cones follow

amazingly invariant routes, after which they unerringly innervate a specific section of a particular target and form a distinctly shaped presynaptic arbor. Wild-type axons are able to innervate their targets with almost perfect reliability, even despite developmental delays. Without redundancy, it is hard to believe that reliable innervation results from a long series of chancy guidance and target selection "choices" involving transiently expressed cues. For example, even if the error rate at any particular decision point were only 0.01, almost one quarter of the NMJs would show an aberration after only two dozen "decisions." But most developmental biologists also accept the theory that connectivity is determined through the use of combinatorial "codes," with growth cones and their postsynaptic targets each displaying a unique set of molecules that allow them to recognize each other. The presence of unique combinatorial codes and redundancy do not seem compatible, however. The already staggering number of unique codes required for connectivity in the nervous system becomes even more unmanageable if redundancy is involved. Accordingly, we believe that developmental biologists are still missing something fundamental in our concepts of pathfinding and target selection.

Following pathfinding and target recognition, we still know almost nothing about the signals and mechanisms involved in the conversion of a growth cone into a synapse. Although a few candidate molecules have been implicated in this conversion process (e.g., the neural tetraspanin Late Bloomer (Lbm; Kopczynski *et al*., 1996), we have no clear models on how such molecules function. The few early reports (see, for example Fradkin, 2002) have mostly not been followed up. Thus, the interface between neuromuscular target recognition and the initiation of synaptogenesis seems unduly neglected, despite the detailed characterization of the process at the level of cell morphology (Yoshihara *et al*., 1997). What role does the postsynaptic cell play in signaling this transition? What is the nature of the intercellular signals? How do such signals regulate the synthesis and localization of the diverse new proteins needed for synaptic function? Once pre- and postsynaptic cells recognize their partner as "appropriate," exactly how do they initially build a synapse? Studies on mammalian neurons indicate that active zones are preassembled in large "Piccolo-Bassoon transport vesicles" (PTVs; Piccolo and Bassoon are protein components of these vesicles with undefined function) (Shapira *et al*., 2003). Active zones are inserted preformed when one of these vesicles fuses with the cytoplasmic membrane. Since proper orientation of active zones requires a properly differentiated postsynaptic partner, these PTVs must somehow be targeted to the appropriate location using transsynaptic cues from the postsynaptic cell, or the active zones must quickly migrate to the correct location after random insertion, and then anchored opposite the postsynaptic cell. Clearly homologous genes encoding the PTV proteins Piccolo and Bassoon have not been identified in the *Drosophila* genome, however, and PTVs have not been shown to exist in insects.

On the postsynaptic side of the NMJ, there is an extremely short list of molecular players. Both biochemical and genetic approaches need to be employed to gain perspective on the number of molecules composing the postsynaptic density (PSD). One obvious priority is the identification of the junctional and extrajunctional GluR channel subunits. Two decades ago, the study of glutamate receptors was essentially synonymous with the study of insect (or at least arthropod) glutamate receptors. Since then, however, it is embarrassing how little progress has been made with regard to insect GluRs in the face of the great strides accomplished by mammalian glutamatergic synapse aficionados. Without knowing the insect receptor subunits, we cannot determine how each is synthesized, how they assemble, and how the receptors are localized. We also need the complete list of subunits in order to ask whether there is a developmental shift in receptor composition, comparable to the situation with AChRs at the vertebrate NMJ. We know even less about the classes, localization, or function of other types of receptors, such as metabotropic GluRs, peptide and nonpeptide receptors, which control a range of downstream signaling cascades.

There are also large gaps in our lists of presynaptic proteins. For example, no molecules have yet been identified as restricted components of the active zone. The molecular nature of the T-bar remains unknown. What is the function of the T-bar? Is it required for targeted SV exocytosis or any other aspect of presynaptic function? Similarly, are there distinctive "active zones" of other presynaptic functions (e.g., SV endocytosis)? Multiple Ca^{2+} and K^{+} channels play crucial roles in the development of efficacy and plasticity at the NMJ on both sides of the cleft. How do these channels get specified and targeted to the correct membrane domain? Do PDZ domain proteins adequately explain how channels become correctly associated with other membrane and membrane-associated proteins to generate localized assemblies required for efficient synaptic transmission? If so, what is the full complement of PDZ domain proteins in

the pre- and postsynaptic cells, and how do they interact to compartmentalize functional domains? Although the presynaptic terminal has been defined in terms of active and periactive zones, the true functional nature of this division remains unknown. Is the periactive zone a functional compartment or is it merely the zone defined as being outside of the active zones? The questions regarding the nature of such functional domains and the ways in which they are established during synaptogenesis are particularly important.

In *Drosophila* there is now plenty of evidence for the existence of multiple transsynaptic signals traveling in both anterograde and retrograde directions. In the embryo, for example, an anterograde signal establishes the GluR field by inducing both GluR clustering and *de novo* GluR synthesis (Broadie and Bate, 1993b), while a retrograde signal dictates the placement of presynaptic active zones opposite their muscle targets (Prokop *et al*., 1996). In the larva, modification of postsynaptic GluR function leads to a compensating change in presynaptic neurotransmitter release (Davis *et al*., 1998; DiAntonio *et al*., 1999; Haghighi *et al*., 2003). What are the signals and receptor mechanisms in these diverse signaling situations? Identification of the transsynaptic signals mediating synaptogenesis and matching presynaptic input to postsynaptic responsiveness is a major challenge. Is there a functional analog of Agrin at glutamatergic synapses? Is even the concept of a secreted signaling mechanism correct? Alternate transmembrane signaling mechanisms (e.g., Neuroligin-Neurexin signaling) have been compellingly proposed for the induction of presynaptic differentiation, but, so far, genetic support for such models has not been forthcoming and these mechanisms remain unexplored in insects.

The primary focus of this chapter has been the maturation of the type I glutamatergic NMJ in *Drosophila*. Essentially nothing is known about the functional development of other classes of synapse. How, when, and why do the different types of NMJ bouton become morphologically, functionally, and molecularly distinct? Are different mechanisms involved in modulatory synapse formation, compared to fast excitatory (glutamatergic) synapses? In *Drosophila* we have a single candidate protein, dCAPS (Renden *et al*., 2001), which appears to be required for all peptidergic transmission. Are there other molecules specifically required for DCV formation and SV fusion? How are these molecules targeted to specific active zones? The investigation of modulatory synapse formation and function represents a major growth area.

In recent years, the first attempts have been made to examine CNS function and functional development in *Drosophila*. These advances are crucial to any true, integrated understanding of neural circuit formation and function utilizing the *Drosophila* genetic system. Very preliminary work to date has focused on three tasks. First, the functional properties of mature neurons and the nature of CNS synaptic communication have begun to be described (Baines and Bate, 1998; Baines *et al*., 1999; Rohrbough and Broadie, 2002; Baines, 2003; Rohrbough *et al*., 2003). A crucial need is to define circuits in which synaptic transmission can be driven, recorded, and modulated. Second, the wiring diagram of connectivity in the CNS has begun to be elucidated (Godenschwege *et al*., 2002; Lohr *et al*., 2002; Marin *et al*., 2002; Komiyama *et al*., 2003; Landgraf *et al*., 2003; Rohrbough *et al*., 2003; Scott *et al*., 2003). This work involves the definition of the functional compartments in the CNS, the mapping of the location and nature of the synaptic connections and, ultimately, the definition of neural circuits. The third, least advanced area is charting the normal development of function within CNS circuits (Baines and Bate, 1998; Allen *et al*., 1999; Baines *et al*., 1999). As with the NMJ, a firm grasp of the normal developmental processes is a basic prerequisite to any attempt to unravel mutant phenotypes. These early studies need to be supported and encouraged. The *Drosophila* NMJ is inherently important as a model for understanding the insect NMJ, as well as a more general model of the glutamatergic synapse. But with regard to understanding the development of general synaptic properties, the NMJ is but a foot in the door. It is time for *Drosophila* neurobiologists to grapple with the complexity of functional development and plasticity within the CNS.

Acknowledgments

The authors would like to thank Matthias Landgraf, Jeffrey Rohrbough, Kale Bodily, and Warren Davis for the images shown in Figure 2. We also appreciate the input from many other scientists who shared unpublished results, insights, and discussion.

2.4 Hormonal Control of the Form and Function of the Nervous System

J W Truman, University of Washington, Seattle, WA, USA

2.4.1. Introduction

Nervous systems are notable for the diversity of cell types they contain and for the specificity of connections made between these cells. This complexity arises from a diversity of local signaling systems beginning with those that select cells to become the stem cells that generate neurons and glia, progressing through a blend of short-range and long-range attraction and repulsion factors involved in axon guidance (e.g., Tessier-Lavigne and Goodman, 1996; **Chapters 1.10** and **2.3**), and ending with systems that mediate target recognition and synapse stability (see **Chapters 1.10–1.12, 2.1, 2.3**, and **2.6**). Besides this plethora of local signaling systems, the nervous system also makes use of "global" cues provided by the endocrine system. At first sight, the widespread presence of a hormone in the blood would seem to be unsuitable for the individualized responses that are the hallmark of central nervous system (CNS) development. Hormones, though, have essential roles in coordinating development across the organism and in linking environmental information with developmental programs.

The most obvious role of hormones is associated with their wide distribution within the organism, which enables them to maintain developmental coordination between distant regions of the CNS and between the CNS and the periphery. In establishing this coordination, they often serve as "gatekeepers" via hormone-sensitive mechanisms that control the ability of neurons to transition from one phase of development to the next. In this regard, hormones provide us with important experimental tools to identify key transition points in neuronal development, and lead us to the switch genes that oversee these transitions. Global signaling, though, can come into conflict with the need for individualized timing differences in the nervous systems so that neural circuits can be assembled in their appropriate sequence. The diversification of hormone receptors and temporal regulation of expression of receptor isoforms provides a mechanism by which individual cellular responses can be adjusted

in time despite the global landscape of hormone titers.

Attempt is made to take a comparative and evolutionary perspective in writing this review. Most of the complex hormone–neuron interactions that are studied in insects are in the context of metamorphosis in the holometabolous orders. In ancestral forms, though, most of these processes occur during embryogenesis and may, or may not, have been under hormonal control. In this regard, the actions of hormones in embryos of both basal and derived insects need to be better understood before we can understand how ancestral embryonic systems were modified to produce the larval stage, whether hormones had a role in these modifications, and how the endocrine system "captured" these developmental pathways and put them under hormonal control. Consequently, the author has started with the embryo in the discussion of these systems, and has tried to highlight where we have serious gaps in knowledge.

Because of limitations in length, the scope of this review has been narrowed to systems for which some knowledge of the cellular or molecular changes is available, and the review is confined to hormonal effects that fall within the developmental realm. Other issues such as the regulation of the complex behavioral tasks at ecdysis (see **Chapter 3.1**) and the complex polyphenisms shown by social insects (see **Chapter 3.13**) have been covered in detail in this volume. Also, this treatment has an extreme "neurocentric" focus. Glial cells have a crucial role in development of the CNS, but they have largely been omitted from this review. An excellent review of the role of glial cells in neuronal development has been written recently by Oland and Tolbert (2003; see also **Chapters 1.10** and **2.3**).

2.4.2. Patterns of Development of the Insect Nervous System

Although insects vary in their early embryonic development in terms of how body segments arise (i.e., short versus long germ-band insects), they are remarkably similar by the time they start to build their CNS at the extended germ band stage (e.g., Thomas *et al.*, 1984; see **Chapters 1.10**, **1.11**, and **2.3**). Studies on grasshopper embryos provided initial insights into how the nervous system is constructed. The cellular composition of the central ganglia is determined by an interplay between neurogenesis and programmed cell death (see **Chapter 2.5**). The neurons arise from large neuronal stem cells, the neuroblasts (NBs), which enlarge and move inward from the ventral neuroectoderm. As seen in **Figure 1**, each NB undergoes repeated asymmetric divisions, producing a series of ganglion mother cells (GMCs), each of which then divides once to produce two daughter neurons. Although the existence of NBs and their pattern of division had been known for over 100 years, a milestone in the field was the publication by Bate (1976a) showing that NBs are arranged in stereotyped arrays that were invariant from individual to individual, and that each NB could be identified uniquely based on its position in this array (see **Chapter 1.10**). The NB arrays are almost identical from segment to segment but those in the thorax typically generate more neurons than their abdominal counterparts (Shepherd and Bate, 1990). The NBs were first identified in terms of position alone but later studies in *Drosophila* showed that each NB expresses a unique combination of molecular markers (Doe, 1992) and the same NB typically shows similar markers in diverse species (Broadus *et al.*, 1995).

Two aspects of neurogenesis are important for comparative studies of the CNS. First, the types of neurons arising from a particular NB are unique to that stem cell, and the destruction of the stem cell results in the failure of these neurons to appear (e.g., Taghert *et al.*, 1984; **Chapter 1.10**). Therefore, the neurons in a hemiganglion arise in 31 autonomous clones, each being a product of a single NB; **Chapter 1.10**. Second, the arrays of NBs have been extremely stable through evolution. The set found in embryos of very basal insects, such as silverfish (Truman and Ball, 1998), is identical to that in grasshoppers and is very similar to that found

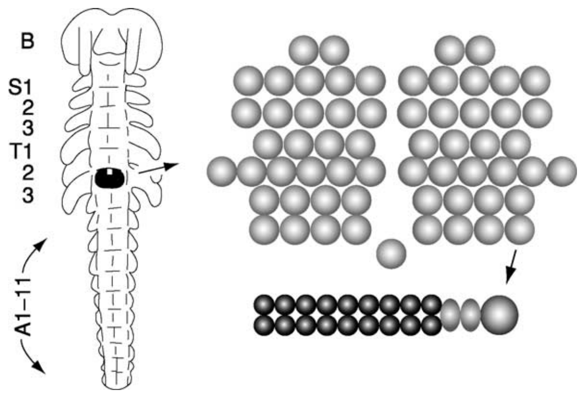

Figure 1 Drawing of a grasshopper embryo showing the segmental arrangement of the neuroblasts (NB) that produce the neurons of the CNS. Asymmetrical divisions by the NB produces a sequence of ganglion mother cells (GMC), each of which then divides to produce two daughter neurons.

in advanced insects such as *Drosophila* (Doe, 1992). Also, a given NB appears to produce similar types of neurons in diverse groups of insects (Thomas *et al*., 1984; Witten and Truman, 1998). This conservation allows a level of comparative analysis that is unrivaled by any other cells or tissues in insects. Most work on neuronal lineages has dealt with the relatively simple segmental ganglia, but rapid strides are being made in establishing the lineage relationships in the brain and in lineage comparisons between species (e.g., Urbach and Technau, 2003).

Within a lineage, the identity of a neuron depends on the birth order of the GMC from which it arises (Kuwada and Goodman, 1985). Brody and Odenwald (2000, 2002) showed that as they divide, the NBs progress through a stereotyped program of gene expression, including *hunchback* (*hb*), *Krüppel* (*Kr*), *POU domain protein* (*pdm*), and *caster* (*cas*) – a set of genes that were used earlier to establish regions of the body (see **Chapter 1.8**). Each GMC retains the expression of the gene activated at the time of its birth and passes it on to its progeny. Studies by Isshiki *et al*. (2001), using mutation and gain-of-function approaches, showed that these genes do indeed provide the information by which a neuron is informed of the birth-order of its GMC, and, hence, determine its identity.

Cell death also plays a prominent role in sculpting segmental differences within the CNS. For example, the leg motoneurons are generated in both thoracic and abdominal lineages, but they degenerate in the abdominal segments (Whitington *et al*., 1982). Also, Thompson and Siegler (1993) showed that the difference in the number of neurons in the thoracic versus the A1 version of the median NB lineage is due primarily to differential neuronal death (see also **Chapter 2.5**).

The first-born neurons serve a pioneer role as they establish the major pathways within the CNS and out into the periphery (Bate, 1976b; **Chapter 1.10**). The progressive events of axon pathfinding, target recognition, and synaptogenesis then bring about the orderly construction of neural circuits (see **Chapter 2.3**).

2.4.2.1. The Hemimetabolous Pattern of CNS Development

Our understanding of nervous system development in hemimetabolous insects is based primarily on studies of orthopteroid insects such as crickets, grasshoppers, and cockroaches, in which the body form of the nymph differs little from that of the adult except that it lacks functional wings and genitalia. Unfortunately, we have little metamorphic data for the CNS from groups like dragonflies and mayflies, in which the nymphal and adult forms are more disparate. In orthopteroid orders, the NBs generate their entire lineage of neurons prior to hatching and; consequently, the nymph hatches with a full set of central neurons. The only regions known to add neurons after hatching are the mushroom bodies and the optic lobes. The mushroom bodies are associated with various types of learning, and certain species continue to add mushroom body neurons even in the adult (e.g., in the cricket *Acheta domesticus*; Cayre *et al*., 1996). The neurogenesis in the optic lobes provides the new interneurons needed to deal with the rows of ommatidia that are added during nymphal molts.

At the time of hatching, neurons already have a dendritic shape characteristic of the adult cell (e.g., Shankland and Goodman, 1982; Boyan, 1983; Kutsch and Heckmann, 1995) although they are only a fraction of their adult size (see **Chapters 1.10** and **2.3**). This similarity is not surprising for neurons having similar roles in the nymph and the adult, but it was not expected for neurons involved in unique adult behaviors such as flight (**Figure 2**; Kutsch and Heckmann, 1995) and reproduction. Not only do these neurons have their adult morphology, but the adult behavioral circuits, have already been assembled by hatching, even though the insect may not show the behavior until weeks or months later, when it finally attains its adult morphology. For example, a newly hatched locust shows the typical flight posture when suspended without tarsal contact, and generates rhythmic alternating bursts by the motoneurons that will supply the elevators and depressor muscles, even though these muscles are undeveloped in the early nymph and there are no wings to move (Stevenson and Kutsch, 1988). Similarly, pharmacological treatment of the terminal ganglia of female grasshoppers can already elicit an "adult" oviposition motor pattern from the embryonic ganglion (Thompson, 1993).

Although the CNS is stable in terms of the number of interneurons, additional sensory neurons are added to the periphery at each molt. Consequently, as the nymph grows, a constant number of interneurons are faced with an increasing number of sensory neurons competing for synaptic space. A well studied example involves the medial giant interneuron (MGI) that receives direct synaptic contact from the filiform hairs on the cercus in the house cricket, *A. domesticus*. As the number of filiform hairs increases with each nymphal molt, the dendrites of MGI must provide additional synaptic space to accommodate the expanding sensory input. An interesting issue with this growth, though,

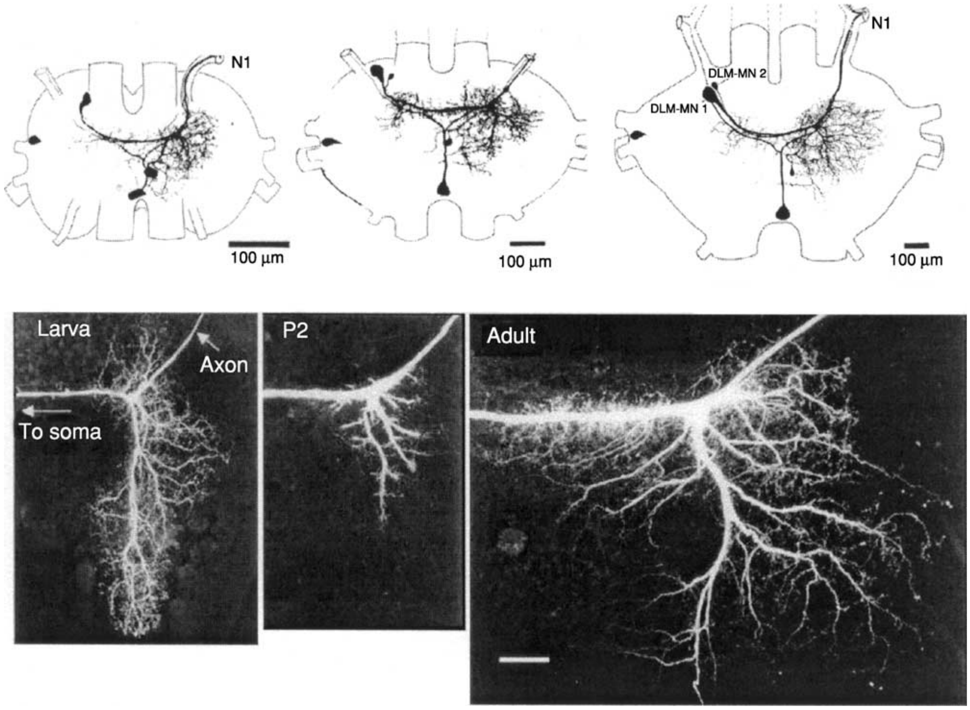

Figure 2 Postembryonic development of flight motoneurons in a hemimetabolous insect (top) *Schistocerca gregaria* and a Holometabolous insect (bottom), the moth *Manduca sexta*. The grasshopper neurons in the late embryo (left), 3rd instar nymph (middle), and adult (right) are revealed by backfilling with cobalt ions from the nerve leading to the site of the dorsal longitudinal flight muscles. The major cells filled include a large dorsal unpaired midline neuron that is neuromodulatory and one of the large motoneurons to the flight muscles (DLM-MN1). The overall structure of this neuron changes very little during postembryonic life. (Modified from Kutsch, W., Hechmann, R., **1995**. Homologous structures, exemplified by motoneurons of Mandibulata. In: Breidbach, O., Kutsch, W. (Eds.), The Nervous Systems of Invertebrates: An Evolutionary and Comparative Approach. Birkhauser Verlag, Basel, pp. 221–248.) Photomicrographs show the dendritic arbor of the moth motoneuron that is the homolog of DLM-MN1. The neuron has a well-developed dendritic arbor in the larva. The arbor is pruned back in the pupa and an extensive adult-specific arbor then forms during adult differentiation. (From Duch, C., Bayline, R.J., Levine, R.B., **2000**. Postembryonic development of the dorsal longitudinal flight muscle and its innervation in *Manduca sexta*. *J. Comp. Neurol. 422*, 1–17.)

is that a sensory hair's transduction properties change as it grows longer: short hairs are sensitive to wind acceleration but as they grow longer they become more sensitive to wind velocity. The MGI is sensitive to stimulus acceleration and newly born, short hairs make strong connections onto this interneuron. With successive molts, as the hair grows longer, the strength of synaptic connections that its neuron makes on the MGI wanes but the same neuron strengthens its synapses onto velocity-sensitive interneurons such as IN 10-3 (Chiba *et al.*, 1988). Hence, some sensory neurons show striking plasticity during growth and remodel their synapses to accommodate the changing properties of their sensory apparatus (see **Chapters 1.10** and **1.11**).

At the time of metamorphosis, there is a qualitative change in the sensory system, with the addition of new sensilla associated with adult-specific structures, like wings and genitalia. Also, to a lesser extent, there is a loss of sensilla that function only in the nymph.

2.4.2.2. The Holometabolous Pattern of CNS Development

The evolution of the holometabolous larva has been accompanied by a number of innovations in CNS development including proliferative and developmental arrests to accommodate the delayed production of the adult form (Figure 3). Also, embryonic neurons do not immediately assume an adult shape but acquire a novel morphology and connectivity to accommodate the larval body.

A fundamental change that occurred during embryogenesis is the truncation of neurogenesis. Rather than generating their entire lineage of neurons during embryogenesis, the NBs produce an initial set of neurons and then arrest. Their early progeny still pioneer the tracts and commisures to provide the basic architecture of the neuropils (Thomas *et al.*, 1984), and most then function in regulating the behavior of the larva. The majority of their progeny, though, are produced well after hatching.

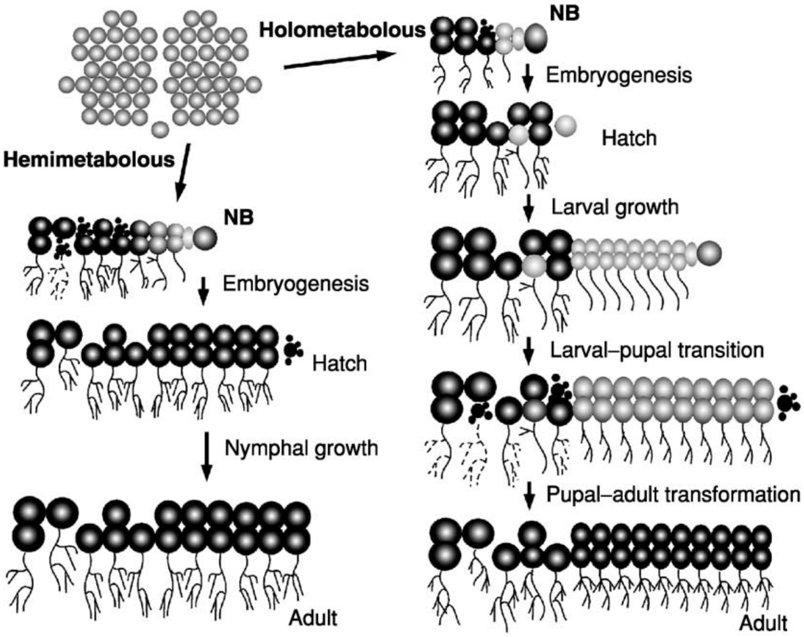

Figure 3 Summary of the changes in the development of neuronal lineages that accommodated the shift from a hemimetabolous to a holometabolous pattern of development. In the ancestral, hemitabolous condition each neuroblast (NB) generated its entire lineage of neurons during embryogenesis, and, during the process, some of the progeny were removed by programmed cell death. With the evolution of the holometabolous larva, the neuroblasts generate only the early portion of their lineage. Some of these progeny arrest as immature neurons (light colored progeny) and cell death is prevented in some of the neurons that normally died in ancestral forms. Neurogenesis resumes during larval life but the newly-born neurons are stockpiled at an early stage in their development. The onset of metamorphosis then stimulates the development of the arrested neurons as well as cell death and dendritic and axonal pruning in the larval neurons. Adult-specific arbors are then elaborated during the pupal–adult transformation.

The extent of cell death may also have been modified to accommodate metamorphosis. In grasshoppers, a thoracic ganglion has about fivefold more neurons than its abdominal counterpart. This disparity arises during embryogenesis, in part from abdominal NBs undergoing fewer divisions than thoracic ones (Shepherd and Bate, 1990) but also from enhanced cell death in the abdominal lineages (Thompson and Siegler, 1993). By contrast, larvae of holometabolous insects have become "abdominalized" as the abdomen has taken over most or all of the larva's locomotor function, and, accordingly, their abdominal ganglia may have twice as many neurons as in the corresponding ganglia in a grasshopper. In lepidopteran caterpillars, for example, each abdominal ganglion has over 1000 neurons, only a few hundred less than seen in a thoracic ganglion in these larvae. The embryonic neurogenic periods are similar for the thorax and abdomen in caterpillars, which suggests that the extent of embryonic neuronal death does not differ dramatically between the two regions. This numerology presents the interesting possibility that the larval CNS may have acquired the extra neurons that it needed simply by maintaining neurons that normally had died in their hemimetabolous ancestors. These evolutionarily "un-dead" neurons then serve as functional neurons, but then finally undergo their ancestral fate of degeneration as metamorphosis begins and the adult form is established.

A neuron's form and pattern of connectivity in the larva often differs markedly from that seen in the adult (**Figure 2**; Levine and Truman, 1985; Duch and Levine, 2000). Most larval neurons are not just partially differentiated adult cells. They are fully differentiated neurons that have specializations adapted to the larval body plan. Their specializations can include their electrical properties (Duch and Levine, 2000) and transmitters (Tublitz and Slywester, 1990), as well as their morphology and synaptic connections. The difference between a neuron's larval and adult morphology varies widely from cell to cell and likely relates to the divergence in the cell's function between the two stages.

Importantly, not all neurons born during embryogenesis acquire a mature phenotype (see **Chapters 2.2**

and **2.3**). The leg motoneurons in *Drosophila*, for example, are born during embryogenesis but their muscle targets do not appear until metamorphosis. In the larva these neurons are found with a sparse dendritic arbor and an axon that extends into the growing leg imaginal discs. Similarly, the larval form of the indirect flight muscle motoneuron MN5 possess an axon but has no dendrites or peripheral targets (Consoulas *et al*., 2002). It is not known, however, if these "immature" neurons contribute to the functioning of the larval CNS despite their immature appearance.

During larval growth, the arrested embryonic NBs reactivate and generate the remainder of their lineage. The neurons born during this second, postembryonic bout of neurogenesis extend an axon to an initial target but then arrest. They are then stockpiled in this immature condition until the start of metamorphosis (**Figure 4**).

Hence, the larva enters metamorphosis with a CNS composed of larval neurons and arrested, immature neurons of both embryonic and postembryonic origins. Some of the dismantling of the larval nervous system comes about through neuronal death, especially in the abdomen, as the ancestral ratios of thoracic to abdominal neurons are finally achieved. Many larval neurons, though, are remodeled. Their larval dendritic and axonal arbors are pruned back and new, adult-specific arbors grow to achieve the shape and connectivity appropriate for the adult stage (**Figure 2**). While larval neurons are starting their remodeling, the immature neurons initiate their adult outgrowth. These diverse processes are orchestrated by the circulating ecdysteroid titers.

2.4.3. Developmental Hormones and Their Receptors

The developmental hormones in insects are the sesquiterpene juvenile hormones (JHs; see **Chapter 3.7**), and the ecdysteroids, the steroid molting hormones (Gilbert *et al*., 2002; see **Chapters 3.3** and **3.5**). The major circulating ecdysteroids are ecdysone (E), which is released from the prothoracic glands, and 20 hydroxyecdysone (20E), an active metabolite of E made by peripheral tissues. The pattern of hormone secretion in hemimetabolous insects is relatively simple (**Figure 5a**). Periodic surges of ecdysteroids drive the molting from one nymphal stage to the next. The presence of JH maintains the nymphal form, but JH titers decline after the formation of the last nymphal stage, allowing the differentiation of adult characters, when the insect is next challenged with ecdysteroid. JH typically reappears in the adult to regulate aspects of reproduction.

The holometabolous life history is associated with a more complex pattern of hormone secretion (**Figure 5b**). Ecdysteroids still cause molting during larval stages and JH is required to maintain the larval form, its so-called "status quo" function (Riddiford, 1994). The decline in JH at the start of the last larval stage then allows the preparation for metamorphosis. During the last larval stage, small surges of steroid occur, which are too small to induce

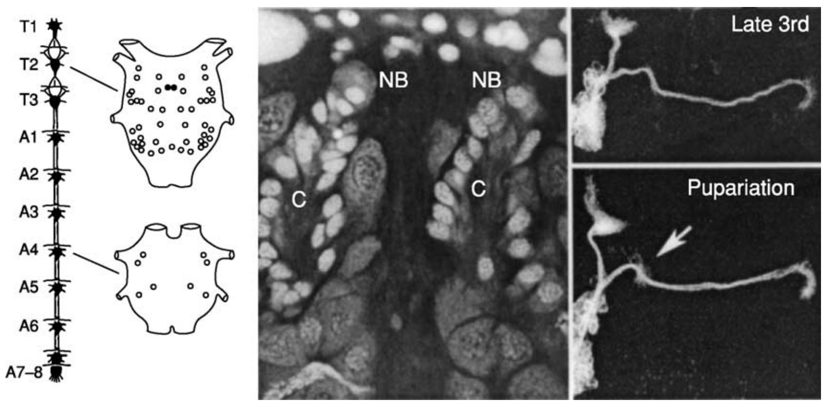

Figure 4 Postembryonic neurogenesis in larvae of holometabolous insects. (Left) Drawing of the ventral nervous system of a *Manduca* larva showing the location of the reactivated embryonic neuroblasts. A thoracic ganglion has about 20 more neuroblast pairs than does an abdominal ganglion. The locations of the paired ''F'' neuroblasts are indicated by the black circles. (Middle) A confocal section showing a dorsal view of a thoracic ganglion stained with propidium iodide showing DNA and RNA. The section shows the 2 ''F'' neuroblasts (NB) and their respective clusters (C) of arrested, adult-specific neurons. (Right) Dorsal views of *Drosophila* thoracic neuromeres showing the postembryonic progeny of a single neuroblast that expresses green fluorescent protein (GFP). The immature neurons extend axons either to the next anterior neuromere or across the midline to a contralateral site. The cells only begin to sprout dendrites (arrow) when metamorphosis begins at pupariation.

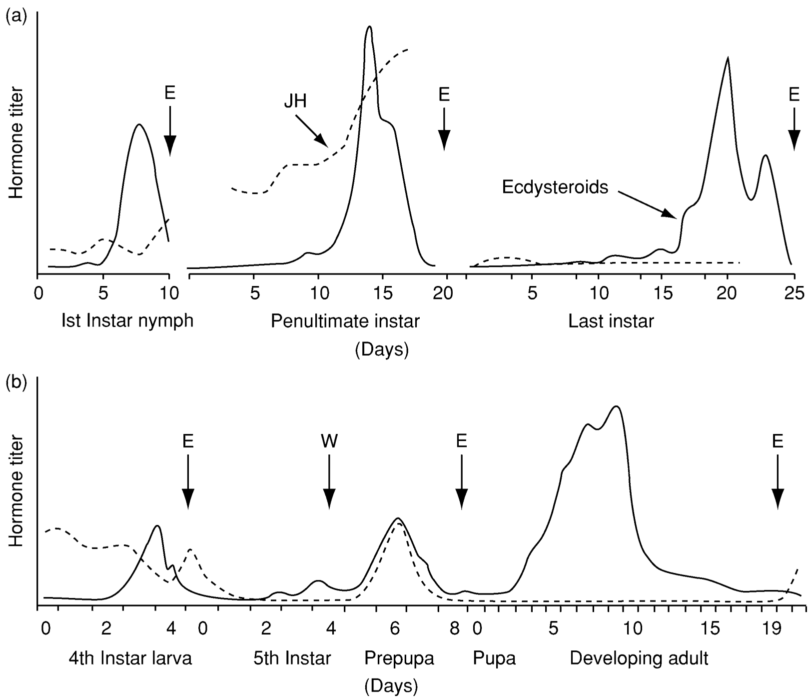

Figure 5 Juvenile hormone (dotted line) and ecdysteroid (solid line) titers in (a) a hemimetabolous insect, the cockroach *Nauphoeta cinerea* and (b) a holometabolous insect, the moth *Manduca sexta*. E, ecdysis; H, hatching; W, wandering. (Titers based on Lanzrein, B., Gentinetta, V., Abegglen, H., Baker, F.C., Miller, C.A., *et al.*, **1985**. Titers of ecdysone, 20-hydroxyecdysone and juvenile hormone III throughout the life cycle of a hemimetabolous insect, the ovoviviparous cockroach *Nauphoeta cinerea*. *Experientia 41*, 913–917; and Riddiford, L.M., **1994**. Cellular and molecular actions of juvenile hormone. I. General considerations and permetamorphic actions. *Adv. Insect Physiol. 24*, 213–274 (review).)

molting but nevertheless direct premetamorphic programs in tissues (Wolfgang and Riddiford, 1986). The largest of these small peaks, the commitment peak, terminates larval feeding, causes wandering behavior, and commits larval tissues to pupal differentiation (Riddiford, 1994). The latter is significant because it renders larval tissues insensitive to subsequent exposure to JH. A major ecdysteroid peak then causes the formation of the pupal stage. This peak is accompanied by the reappearance of JH which acts on selected imaginal tissues to prevent their premature adult differentiation (Williams, 1961; Kiguchi and Riddiford, 1978; Champlin *et al.*, 1999). In higher flies, like *Drosophila*, this large ecdysteroid peak also causes the larval cuticle to transform into a protective case, the puparium, inside of which the true pupal stage forms. JH disappears prior to pupal ecdysis and a prolonged surge of ecdysteroids then drives adult differentiation. In *Manduca*, the major circulating steroid at the beginning of adult differentiation is E but 20E then becomes prominent as metamorphosis progresses (Warren and Gilbert, 1986). As with hemimetabolous insects, JH then returns in the adult, typically in association with some aspect of reproductive control (see **Chapters 1.3** and **3.9**).

Although the overall patterns of hormone secretion are similar in moths and flies, there are major differences in how their tissues respond to this hormonal landscape. The most striking differences are seen in the response of tissues to JH. Application of exogenous JH during the last larval stage of *Manduca* causes the larva to molt to a supernumerary larval stage rather than to pupa. Also, the application of JH to the pupa, at the outset of adult differentiation, results in a second pupal stage, although some adult features may also be present (Riddiford and Ajami, 1973). In *Drosophila*, by contrast, treatment of the last larval stage with JH does not result in an extra larval instar, and an apparently normal puparium and pupa are formed. During subsequent adult differentiation, though, the abdominal epidermis makes a second pupal cuticle, while the imaginal discs in the head and thorax make normal adult structures (Postlethwait, 1974; Riddiford and Ashburner, 1991). JH also suppresses aspects of adult differentiation of internal tissues including the CNS (Restifo and Wilson, 1998; Williams and

Truman, 2004). Hence, in higher flies, JH sensitivity is lost during the larval pupal transition and appears only in selected tissues during the differentiation to the adult.

The changing sensitivity of tissues to hormonal signals could be encoded at the level of their receptors. In the case of JH, though, the issue is unclear because a JH receptor has yet to be unequivocally demonstrated (see **Chapter 3.7**). Indeed, multiple receptor systems might be involved in mediating the action of this versatile hormone (Wheeler and Nijhout, 2003). By contrast, the receptors that mediate ecdysteroid action have been known for over a decade (Koelle *et al.*, 1991; see **Chapter 3.5**), and receptor distributions direct the time and nature of a cell's response to this steroid.

The action of ecdysteroids is mediated through a heterodimer of two members of the nuclear receptor family, the Ecdysone Receptor (EcR) and Ultraspiracle (Usp) (see **Chapter 3.5**; Riddiford *et al.*, 2000 for reviews). Like other family members, EcR has a DNA binding domain consisting of two Zn fingers, and a ligand binding domain that carries an activation function (the AF2 domain) that mediates ligand-dependent activation. The *Ecr* gene encodes different protein isoforms that share a common DNA and ligand-binding domain, but differ in their N-termini. *Drosophila* has three isoforms, EcR-B1, -B2, and -A, whereas other Diptera and Lepidoptera have only two isoforms, EcR-B1 and -A. Cell transfection experiments have shown that the A/B regions of EcR-B1 and -B2 have potent AF1 activation domains, whereas this region of EcR-A appears to have a repressive function (Mouillet *et al.*, 2001; Hu *et al.*, 2003).

The EcR/Usp complex binds to specific DNA response elements. The unliganded receptor binds corepressors and mediates local transcriptional silencing. With binding of ligand, coactivators are assembled allowing transcriptional activation. Transcriptional activation can be mediated through two regions of the receptor – through the AF1 site in the A/B region (causing "ligand-independent" activation) and the AF2 site in the LBD. The coactivator and corepressor complexes include a number of components, many of which participate in multiple signaling pathways. They may interact with the core promoter and/or locally modify the chromatin (e.g., through acetylation or deacetylation of histones) to facilitate or suppress transcription (review: Kraus and Wong, 2002).

EcR mutant and receptor misexpression studies indicate that the receptor isoforms have both unique and overlapping functions (Bender *et al.*, 1998; Schubiger *et al.*, 1998; Li and Bender, 2000; Cherbas *et al.*, 2003). Since EcR-A and EcR-B1 show dramatic differences in their distribution in both time and space, their expression and action is a key to understanding how different neurons may show differing responses to the same hormonal signal.

2.4.4. Hormones and the Generation of the Larval CNS

The specializations that brought about the larval CNS include the truncation of neurogenesis, a suppression of neuronal death, and an alteration in the growth patterns of embryonic neurons. The roles that ecdysteroids and JH may have had in these events, though, are poorly understood. During embryogenesis, holometabolous insects show a precocious appearance of JH relative to that seen in embryos from hemimetabolous groups. This early appearance of JH is thought to be associated with the truncation of growth and premature differentiation that was necessary to generate the novel larval stage (Truman and Riddiford, 2000; Erezyilmaz *et al.*, 2004). At this point, though, the linkage between key developmental switches in the CNS and the hormone titers stands only as a correlation.

A striking feature of the neurogenesis in embryos of both *Drosophila* and Lepidoptera is its abrupt arrest that occurs at about 50% of embryogenesis (e.g., **Figure 6**). This arrest contrasts with the pattern seen in ametabolous and hemimetabolous insects, in which some neuroblasts continue proliferation until almost hatching (Shepherd and Bate, 1990; Truman and Ball, 1998), and is consistent with there being an extrinsic signal responsible for the arrest. The arrest occurs at the time that the rising embryonic ecdysteroid titer causes the production of the first larval cuticle. Therefore, this embryonic ecdysteroid surge may be responsible for the arrest, but experimental data are needed to support this speculation.

2.4.5. Nervous System Changes during Larval or Nymphal Growth

2.4.5.1. Somatic Sensory Systems

An initial set of sensory neurons differentiate during embryogenesis in both larvae and nymphs. These include proprioceptors, such as stretch receptors and chorditonal organs, that monitor body wall stretch and joint position, and external sensory organs with cuticular hairs and having mechano- or chemoreceptive functions (see **Chapters 1.11, 1.12**, and **3.15**). This initial set of receptors is highly stereotyped and homologous cells can be found between *Schistocerca gregaria*, *Drosophila* (Meier

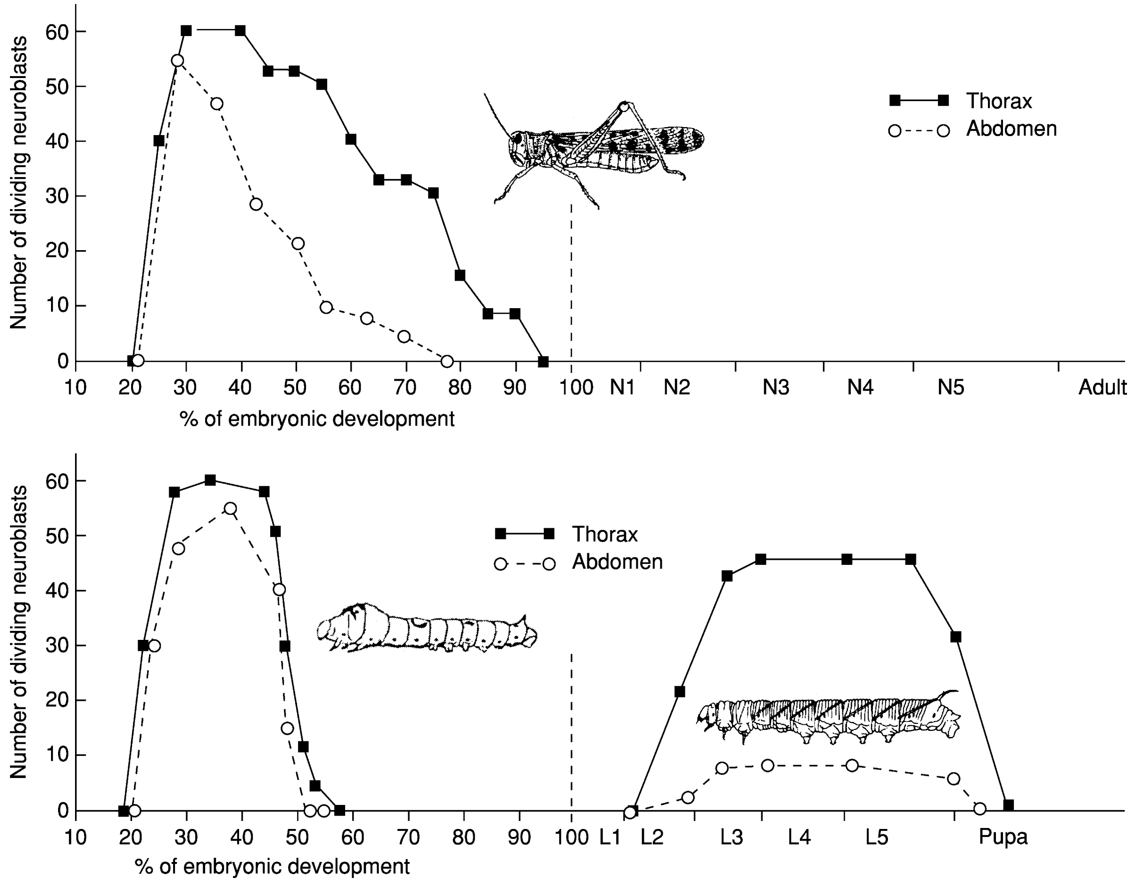

Figure 6 Comparison of the duration of neurogenesis in a hemimetabolous insect, the grasshopper *Schistocerca gregaria*, and in holometabolous lepidopteran larvae. (The grasshopper data are based on Shepherd, D., Bate, C.M., **1990**. Spatial and temporal patterns of neurogenesis in the embryo of the locust (*Schistocerca gregaria*). *J. Comp. Neurol. 319*, 436–453, while the lepidopteran data are based on Booker, R., Truman, J.W., **1987a**. Postembryonic neurogenesis in the CNS of the tobacco hornworm, *Manduca sexta*. I. Neuroblast arrays and the fate of their progeny during metamorphosis. *J. Comp. Neurol. 255*, 548–559 and J.W. Truman, unpublished data.)

et al., 1991) and *Manduca sexta* (Grueber and Truman, 1999). Typically, the number of proprioceptors usually remains unchanged during the growth of the larva or nymph, but the sensory hairs show dramatic increases in numbers through successive instars (**Figure 7**). The larvae of higher Diptera, though, are exceptional in that they add no new sensory neurons after hatching (see **Chapter 1.11**).

The positions of the first hairs that arise during embryogenesis are very stereotyped, but during the postembryonic period interactions between the epidermal cells and existing sensory hairs determine the placement of new sensory hairs. The studies by Wigglesworth (1940) on the spacing of new sensory hairs in *Rhodnius* provided the first experimental demonstration of lateral inhibition. He showed that existing bristles suppressed the formation of a new sensory organ precursor (SOP) in their immediately vicinity, thereby insuring that new bristles were placed in spaces that lacked them.

The production of new bristles is coordinated with the molt cycle. In *Rhodnius*, the quartet of cells that comprise the sensory organ (SO) appears 6 days after the insect has taken a blood meal, and is associated with a general mitotic peak at the start of a molt (Wigglesworth, 1953). The sensory neuron extends an axon towards the CNS, and the trichogen and tormogen cells that form the cuticular hair and socket, enlarge soon thereafter. The new sensillum appears to be anatomically functional by the time the molt is completed.

Although *Rhodnius* undergoes the steps from the establishment of the SOP to the finished sensory organ within a single molt, the process extends over two molts in large rapidly growing larvae, such as *M. sexta* (Grueber and Truman, 1999). In larvae of *Manduca* each SOP produces five cells including two neurons. One neuron is a typical mechanoreceptor neuron associated with the new bristle but the other is a dendritic arborization (da) sensory

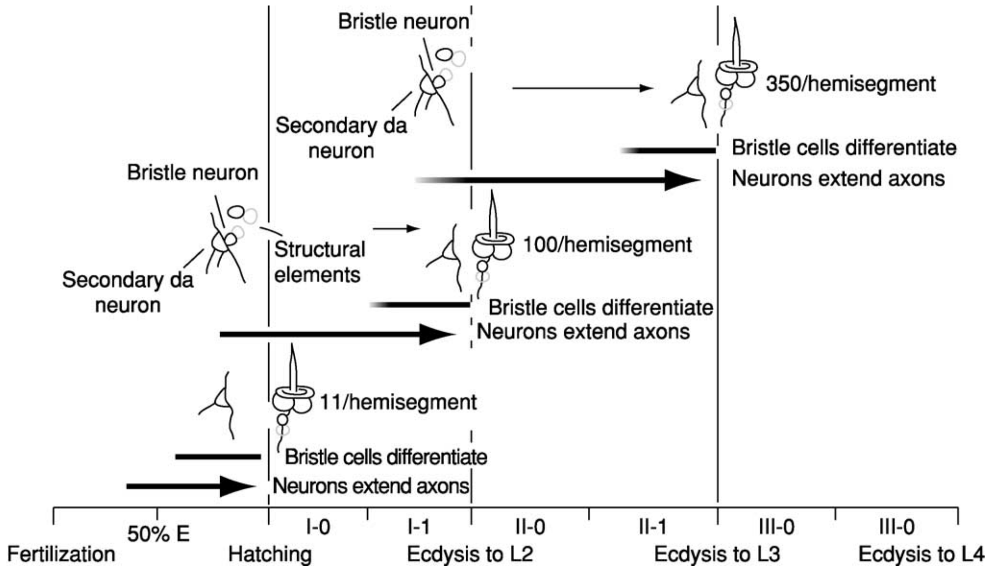

Figure 7 The timing of the birth and differentiation of sensory bristles on the second abdominal segment of *Manduca sexta* caterpillars. The larva hatches with 11 sensory bristles and 12 dendritic arborization (da) sensory neurons. Two waves of sensory neurons are then added, the first prior to hatching and the second during the molt to the second instar. The neurons immediately extend axons to the CNS but the sensory hair does not differentiate until the succeeding molt. No sensory hairs are added after the second wave. (Based on data from Grueber, W.B., Truman, J.W., **1999**. Development and organization of a nitric-oxide-sensitive peripheral neural plexus in larvae of the moth, *Manduca sexta*. *J. Comp. Neurol. 404*, 127–141.)

neuron whose dendrites ramify under the soft cuticle of the larva. At this point, it is not known whether the dense network of processes from the latter is involved in detecting cuticular stretch or in sensing noxious, damaging stimuli. During the first molt the SOP is established and undergoes the divisions to produce the two neurons and three support cells. The cuticular structures made by the trichogen and tormogen then appear at the next molt, in response to the next molting surge of ecdysone (Figure 7). This delay may be necessary in large insects to allow axons from the bristle to grow into the CNS and make connections with their central targets.

2.4.5.2. Growth of the Eyes

In many nymphs new ommatidia are added to the eye at each molt. In *S. gregaria*, for example, the number of ommatidia increases from about 2500 in the newly hatched nymph to over 9000 in the adult. The new ommatidia arise from a region along the anterior margin of the eye, which is divided into proliferation and differentiation zones (Anderson, 1978). The proliferation zone shows a basal level of cell division that probably produces photoreceptor neurons at a constant rate, since outgrowing axons from new photoreceptors are evident at all times during the intermolt and molting periods. At the start of the molt there is an increase in mitoses in the proliferation zone and also a spike of proliferation in the differentiation zone, where the ommatidia are being assembled. The divisions in the differentiation zone, likely produce support cells, such as those that make the crystalline cone and the screening pigments. Except for responses to circulating factors, the growth of the eye is under autonomous control, as illustrated by normal patterns of proliferation being observed in eyes transplanted to the surface of the prothorax (Anderson, 1978).

Unlike nymphs, the eyes of larvae consist of only a small set of separated facets, the stemmata. These likely arose from the most posterior set of ommatidia in the eyes of the ancestral larva. The stemmata, though, add neither facets nor more photoreceptors as the larva progresses through its larval instars. The compound eye of the adult appears only at metamorphosis and forms immediately anterior to the stemmata.

2.4.5.3. New Central Neurons. Regulation of Neurogenesis

In hemimetabolous insects, postembryonic neurogenesis in the CNS is confined to the mushroom bodies and the optic lobes. There is no information as to whether neurogenesis in the mushroom bodies is influenced by ecdysone and molting. In the optic lobe of *Schistocerca*, the production of new neurons for the lamina and the medulla, the outer two optic neuropils, occurs at a constant rate throughout the instar, without any modulation during the time of the molts (Anderson, 1978). This pattern of constant

interneuron production matches the pattern of constant addition of photoreceptor axons in the periphery. While the eye does not need the optic lobes to make new ommatidia, the optic lobes do need the eyes to some extent. In *Schistocerca* the surgical removal of the anterior proliferation and differentiation zones result in no new photoreceptor axons growing into the optic lobe. Despite the lack of ingrowing axons, there appears to be no difference in the rate of division of NB or GMCs for either the lamina or medulla. There is, though, a dramatic effect of cell survival as one sees enhanced death of the lamina ganglion cells (Anderson, 1978). In *Manduca* and *Drosophila*, the relationship between photoreceptor axons and lamina neurons differs from that seen above, because ingrowing axons influence proliferation as well as cell survival (see Section 2.4.8.4).

Postembryonic neurogenesis in the ventral CNS has been studied primarily in *Manduca* (Booker and Truman, 1987a) and *Drosophila* (White and Kankel, 1978; Truman and Bate, 1988), but also occurs in larvae of Coleoptera, Hymenoptera, and Neuroptera (J.W. Truman, unpublished data). Hence, it is a ubiquitous feature of the holometabolous life style. In highly derived larvae, like those of *Manduca* and *Drosophila*, neurogenesis begins early in larval life and concludes shortly after pupal ecdysis (**Figure 4**). The factors responsible for the reactivation of the arrested embryonic neuroblasts are best understood in *Drosophila*. The need for nutritional cues was shown by experiments, in which newly hatched larvae were maintained on a glucose diet that lacked amino acids. On such a diet, the energetic requirements of the larva are met by the sugar but growth is not possible. Under these conditions neuroblasts that are already cycling, such as those of the mushroom bodies, continued to divide, but arrested neuroblasts could not reenter the cell cycle (Britton and Edgar, 1998).

The control over NB activity may not be cell autonomous and may involve the surrounding glia. Mutations in the gene *anachronism* (*ana*), that encodes a cell-surface protein, results in the precocious onset of postembryonic neurogenesis (Ebens *et al*., 1993). Interestingly, *ana* is not expressed in the NB but, rather, it is expressed in the surrounding glia, suggesting that these cells may actively inhibit NB reactivation. The suppression imposed by *ana* appears to be antagonized by the expression of the *trol* gene (*terribly reduced optic lobes*) (Caldwell and Datta, 1998) which acts through cyclin E to allow the transition of the stem cells from G1 into the S phase. The activation of proliferation may also involve the action of ecdysteroids in the early larvae (Datta, 1995; Park *et al*., 2001).

2.4.6. Role of Hormones in the Metamorphosis of Hemimetabolous Nervous Systems

The metamorphic changes seen in hemimetabolous insects are most evident in the peripheral nervous system, because there is an obvious acquisition of adult-specific sensory neurons and, to a lesser extent, the loss of nymph-specific sensilla. An example of the latter is seen in *Rhodnius prolixus*, in which most of the sensory hairs are lost on the dorsum of the adult abdomen since it is covered by the wings. Interestingly, although the cuticular hairs are lost, the sensory neurons that supplied them do not die and persist in the adult (Wigglesworth, 1953). Presumably, they cease to serve as functional sensory neurons since their transducing hairs are no longer present. The topical application of JH prevents both the loss of these nymphal sensory hairs and the appearance of adult-specific sensilla. Another example of JH preventing the appearance of adult-specific sensilla is seen in cockroaches in which JH treatment of the last nymphal stage suppresses the appearance of pheromone-sensitive hairs on the antennae (Schaffer and Sanchez, 1973).

The metamorphic changes in the CNS of hemimetabolous insects are subtle and do not involve massive neuronal death or neuronal remodeling. There may be, however, important functional changes that occur during the molt to the adult (Olberg, 1986). This is seen most strikingly in the visual system of dragonflies. In the adult, there are eight descending visual interneurons that carry wide-field information from the optic lobes down to the thoracic ganglia. These interneurons are also present in the nymph, but only one is functional and the others are electrically silent. They finally become electrically active during the molt to the adult. The one functional interneuron in the nymph receives information from the whole visual field of the nymph, but after metamorphosis those ommatidia now comprise the extreme posterior border of the adult eye, and the interneuron is now responsive only to stimuli and the periphery of the visual field.

2.4.7. Hormones and the Metamorphosis of Holometabolous Nervous Systems

2.4.7.1. Death of Larval Neurons

Most studies on the metamorphic fates of larval neurons have focused on the motor system (see **Chapter 2.5**). The fates of motoneurons, though, need to be considered in the context of their target

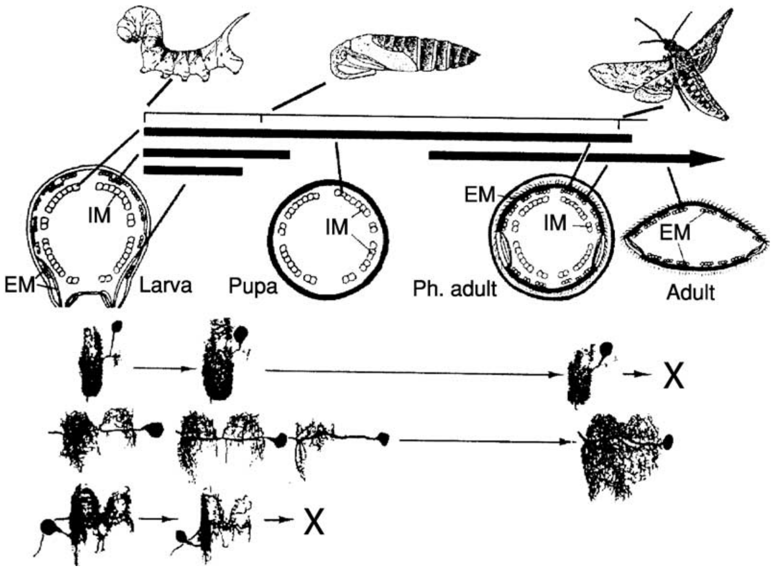

Figure 8 Summary of the fates of larval neurons and muscles during metamorphosis in *Manduca sexta*. (Top) Time-line showing the three major muscle fates during metamorphosis. The cross-section views show the positions of abdominal internal (IM) and external (EM) muscle groups in the larva, pupa, pharate adult (Ph. adult), and adult. The bars show the time when functional muscle is present. Many internal muscles persist through metamorphosis but then die after adult emergence. One group of external muscles die in the prepupa while others degenerate1–2 days after pupal ecdysis. The remains of some of these muscles are used for templates for the growth of adult muscles. (Bottom) Examples of the changes in morphology and survival of motoneurons associated with muscles having the three kinds of fates. (Neuron data from Weeks, J.C., Truman, J.W., **1985**. Independent steroid control of the fates of motoneurons and their muscles during insect metamorphosis. *J. Neurosci. 5*, 2290–2300; and Levine, R.B., Truman, J.W., **1985**. Dendritic reorganization of abdominal motoneurons during metamorphosis of the moth, *Manduca sexta*. *J. Neurosci. 5*, 2424–2431.)

muscles (**Figure 8**; reviews: Consoulas *et al*., 2000a; **Chapters 2.1** and **2.3**). In both *Manduca* and *Drosophila* the larval musculature is dismantled in three steps. An initial bout of degeneration occurs prior to pupal ecdysis, and includes most of the musculature of the head and thorax, and selected muscles in the abdomen. The early loss of the head and thoracic musculature provides space for the growth and expansion of the imaginal discs that will produce parts of the adult head and thorax. A second period of muscle death occurs early in pupal life and involves muscles that were necessary for pupal ecdysis. In *Manduca*, the pupa is then left with a set of internal longitudinal muscles in segments A3 to A6, and these mediate the limited behavior of the pupa. *Drosophila* similarly has a set of “persistent larval muscles” but these lose their contractile machinery through the middle of metamorphosis. The adult muscles begin forming after pupal ecdysis. Some are formed from templates provided by the remains of the larval muscles, while others are formed *de novo* as groups of myoblasts aggregate to found adult muscles. In *Manduca*, the muscles of the head and thorax (except for the indirect flight muscles) are formed *de novo*, whereas most of the abdominal musculature is formed on larval templates. In *Drosophila*, by contrast, the vast majority of the adult muscles arise *de novo*, with the indirect flight muscles being one of the few muscles organized on a larval template (Fernandes and Keshishian, 1998). In both species, at the end of adult development, the abdomen has both persisting larval muscles and the new adult-specific musculature. The larval muscles, along with a few specialized ecdysial muscles, then degenerate a few hours after emergence leaving the animal with its adult-specific musculature.

2.4.7.1.1. Death during the larval–pupal transition Although larval muscles die in three waves, the neurons that innervate them only die at two times (**Figure 8**) (see **Chapter 2.5**). In both *Drosophila* and *Manduca*, most larval neurons die during the initial period that occurs shortly after pupal ecdysis. The most extensive cell loss is seen in the abdominal CNS, reflecting a reduction in the behavioral importance of this region of the body. With the vermiform body of the larva, the abdominal CNS controlled a complex musculature and had the major responsibility for locomotion. At metamorphosis the latter functions are given over to the thorax, and the abdomen becomes

severely reduced both in its musculature and its behavioral capacity.

The most detailed studies of neuronal death during this first period are from *Manduca* and examine the fates of PPR and APR, abdominal motoneurons that control the retraction of the larval prolegs. Two endocrine conditions are needed for the death of PPR: the lack of JH during the commitment peak of ecdysteroids, and the subsequent high 20E titers of the prepupal peak (Weeks and Truman, 1985). Although the death of PPR follows that of its muscle, the neuron's death is not induced by the loss of its target. This conclusion is based on experiments showing that PPR continues to show its appropriate 20E-dependent fate even when its muscle is surgically removed.

An elegant set of *in vitro* experiments using the motoneuron APR confirmed that the degeneration response was not caused by the death of its target. This larval motoneuron undergoes programmed cell death but in a segment-specific context: those in segments A5 and A6 degenerate whereas those in segments A3 and A4 survive (Sandstrom and Weeks, 1998). Neurons taken from larvae and maintained without 20E *in vitro* survive regardless of their segmental origin. When exposed to 20E, however, some undergo programmed cell death, but only if they were removed from segments in which these cells would normally die (Streichert *et al.*, 1997) Thus, the hormone-induced death of these neurons is intrinsically programmed and does not depend on interactions either within the ganglion or with their muscle targets.

2.4.7.1.2. Death during the pupal–adult transition The last wave of neuron and muscle death occurs shortly after adult ecdysis, and primarily involves the ecdysial muscles that will not be needed again in the adult. Post-ecdysial muscle death appears to be a universal feature of adult ecdysis in higher insects, but the loss of their motoneurons is not. In the moth *Hyalophora cecropia*, for example, the intersegmental muscles degenerate but their motoneurons survive through the remainder of adult life (S. Fahrbach, personal communication; see **Chapter 2.5**). The hormonal signals that control the death of these muscles and their motoneurons are varied. In all cases, the decline in ecdysteroids at the end of adult differentiation is an essential component of this control, and late injections with 20E delay the degeneration response. In some species, such as the moth *Antheraea polyphemus*, a peptide hormone provides the final trigger for muscle degeneration (Schwartz and Truman, 1982). In *Manduca*, by contrast, the withdrawal of ecdysteroids alone appears to be sufficient for muscle death.

As with the muscles, the death of neurons in both *Manduca* and *Drosophila* requires a decline in ecdysteroids, and injection of 20E just before adult ecdysis prevents the death (Truman and Schwartz, 1984). The control over the degeneration is complicated, though, because the doomed neurons are involved in both ecdysis and post-ecdysis behaviors, such as wing inflation, and these behaviors can be separated in time if the insect is not given an appropriate site to inflate its wings. Accordingly, in *Manduca*, behavioral manipulations, such as forcing newly emerged moths to dig through soil, result in some neurons dying on schedule but delay the death of others (Truman, 1983). Nerve cord transection experiments in *Manduca* showed that one of the last neurons to die, MN12, requires a descending signal via the nerve cord in order to degenerate (Fahrbach and Truman, 1987). A similar situation appears to hold for some of the doomed neurons in *Drosophila* since decapitation of the newly emerged fly prevents the death of a subset of the cells (Kimura and Truman, 1990; Robinow *et al.*, 1997). Hence, the death of some of the late dying neurons requires both the absence of 20E and a descending signal from the head.

The death of neurons in *Drosophila* is immediately preceded by the appearance of transcripts for the cell death genes, *reaper* and *grim* (Robinow *et al.*, 1997). Focusing on *reaper* expression, these authors showed that the injection of 20E, less than an hour before the transcripts normally appear, blocked both the appearance of *reaper* and the onset of neuronal death. This timing is consistent with the hypothesis that 20E directly suppresses the transcription of these cell death genes. Interestingly, the decapitation of newly emerged flies, which prevents the death of a subset of doomed cells, does not prevent *reaper* transcripts from appearing in these cells (Robinow *et al.*, 1997). Apparently the descending signal acts downstream of *reaper* transcription, perhaps at the level of translation of this protein.

2.4.7.2. Remodeling of Larval Neurons

Figure 9 summarizes the main developmental phases, through which a neuron progresses as it changes from its larval to its adult form. The first changes appear at the larval–pupal transition during the "pruning phase," as neurons rapidly remove axonal and dendritic branches. For the axonal branches of mushroom body neurons and the dendrites of

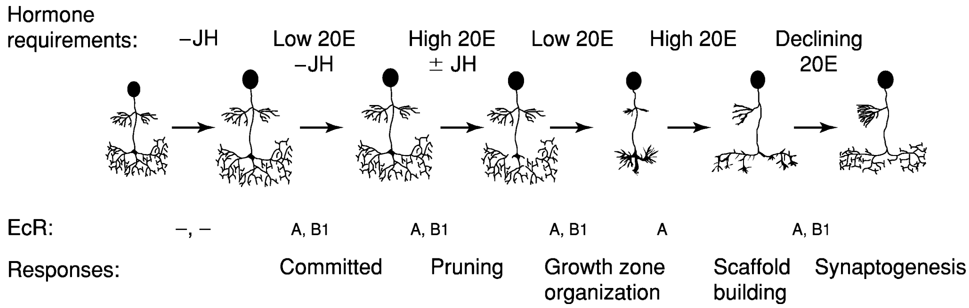

Figure 9 Summary of the developmental changes that occur during the life of a larval neuron during larval growth and metamorphosis. The EcR isoform data were obtained from *Drosophila* and the hormonal requirements are based on studies on *Manduca sexta*. The one process whose endocrine requirements are known to be different in moths and flies is during commitment: JH treatment cannot prevent *Drosophila* neurons from subsequent pruning.

dendritic arborization (da) sensory neurons, pruning occurs as branches are pinched off and undergo fragmentation (Watts *et al.*, 2003; D.W. Williams and J.W. Truman, unpublished data). This process is mediated through the ubiquitin-proteosome pathway (Watts *et al.*, 2003) similar to Wallerian degeneration seen in severed vertebrate axons. Fragmentation is not the only mechanism employed during pruning, though, since time-lapse movies show that the loss of the axonal arbors of the Tv neurosecretory neurons occurs by retraction of the axonal branches (H. Brown and J.W. Truman, unpublished data) more like the more gradual retraction of processes seen during synapse elimination at vertebrate neuromuscular junctions (e.g., Walsh and Lichtman, 2003).

Pruning is followed by a "growth zone organization phase," as the cell prepares for its adult outgrowth. One part of the arbor may show retraction bulbs as pruned stumps are retracted, while another part is enlarging and organizing into a growth cone. This is also a time when soma size increases, a change that is especially obvious for the flight motoneurons (Duch *et al.*, 2000).

The growth cones begin to extend and branch during the "scaffold building phase." *In vivo* imaging of the outgrowth of dendritic arbors from the da sensory neurons show that, as the arbor expands, branch retraction also occurs as the cell establishes the basic "foot-print" of the arbor (Williams and Truman, 2004). Studies on *Manduca* motoneurons show that the outgrowth phase is marked by changes in Ca^{2+} currents in the cell (Duch and Levine, 2000). During the early phase of elongation, Ca^{2+} currents are small and confined to distal ends of extending branches. In the later phases, the cell shows Ca^{2+} spikes that provide Ca^{2+} transients throughout the cell. Eventually, these Ca^{2+} spikes are masked by the appearance of strong K^{+} conductances.

The "synaptogenesis" phase then involves the formation and maturation of synaptic contacts. This phase occupies the last half of adult differentiation.

2.4.7.2.1. The pruning phase and its hormonal control The pruning of larval dendritic and axonal branches in both *Manduca* and *Drosophila* is associated with the large peak of ecdysteroid that causes the transition from the larval to the pupal stage. Ligation and hormone replacement experiments in *Manduca* demonstrated that the pruning of the proleg motoneuron PPR requires two discrete endocrine cues. 20E, acting in the absence of JH at the wandering peak, is necessary to "commit" the neuron to prune, when it is next exposed to high levels of ecdysteroid. The following high 20E titers of the prepupal peak then cause the pruning (Weeks and Truman, 1985). In the case of PPR, dendritic pruning is followed a few days later by the death of the cell. These two responses, though, are triggered separately, since the length of steroid exposure needed to induce pruning is less than that needed to cause cell death (Weeks *et al.*, 1992). Although appropriately, timed treatment with JH mimics can prevent axon and dendritic pruning in *Manduca*, JH is not able to suppress the pruning response in *Drosophila* neurons (Williams and Truman, 2004).

The demonstration that dendritic pruning removes larval-specific synaptic contacts comes from work on the proleg withdrawal reflex in *Manduca* caterpillars. When the plantal hairs on the end of the proleg contact a foreign object, the firing of their sensory neurons (PH-SNs) causes a reflexive withdrawal of the proleg. The PH-SNs make monosynaptic contacts with PPR, the motoneuron that innervates the proleg retractor muscles. Early in metamorphosis, the proleg retraction reflex weakens. This occurs at the time that the proleg retractor muscles are degenerating, but there are also changes

to the synapse between the PH-SNs and PPR. Stimulation of the sensory nerve carrying the axons of the PH-SNs show a marked weakening of synaptic strength associated with the pruning of dendrites of the motoneuron (Jacobs and Weeks, 1990). Localized treatment of a proleg with JH mimics can produce a pupa that carries a larval proleg with its normal complement of plantal hairs. Even though these JH-treated sensory neurons maintain their larval morphology, PPR still prunes back its dendrites with the associated drop in synaptic efficacy. These results argue that the dendritic pruning is a cell autonomous response rather than one that is elicited by changes in presynaptic partners.

Similar attempts to use ecdysteroid-induced mosaics to examine axonal pruning in motoneurons were not as clear cut (Hegstrom and Truman, 1996). In *Manduca*, permanent larval abdomens were established by ligation, and then 20E was applied locally to the epidermis over a muscle to cause local degeneration of the muscle. The muscles showed a mixed early metamorphic response with some fibers regressing and others remaining contractile. The motoneuron arbor withdrew endplates from the regressing fibers but maintained endplates on fibers that were intact. Thus, the regression of the muscle is sufficient to cause the withdrawal of endplates. The unresolved issue, though, is whether target regression is *necessary* for synapse removal to occur. In other words, would suitably hormone primed motoneuron still withdraw contact from a healthy target muscle? Manipulation of steroid receptors, as described in Section 2.4.9.1, suggests that the target response is not necessary for the neuron to prune back dendrites and axons. The loss of endplates described above may be a homeostatic response of the neuron to target degeneration, and may not be relevant to the changes seen during metamorphosis.

2.4.7.2.2. Hormonal control of arbor outgrowth The outgrowth of pruned axonal arbors involves organization of the outgrowth zone followed by scaffold production and synaptogenesis (**Figures 9 and 10**). The ecdysteroid requirements for some of these events have been addressed primarily in *Manduca*. The growth zone organization phase occurs during the first few days of adult differentiation, when the ecdysteroid titer is dominated by ecdysone with relatively low levels of 20E. The concentration of 20E begins its rapid rise about day P + 7 to 8, and correlates with the shift to the rapid branch extension that underlies scaffold building (**Figure 10**). Synaptogenesis begins on about day P + 12 as the 20E titer begins to fall (Truman and Reiss, 1995).

The organization of the growth zone requires the initiation of the adult peak of ecdysteroids, as shown by diapausing pupae, which lack 20E and maintain their neurons in a post-pruning state for months. A growth zone only begins to form, when these pupae are provided with 20E (Truman and

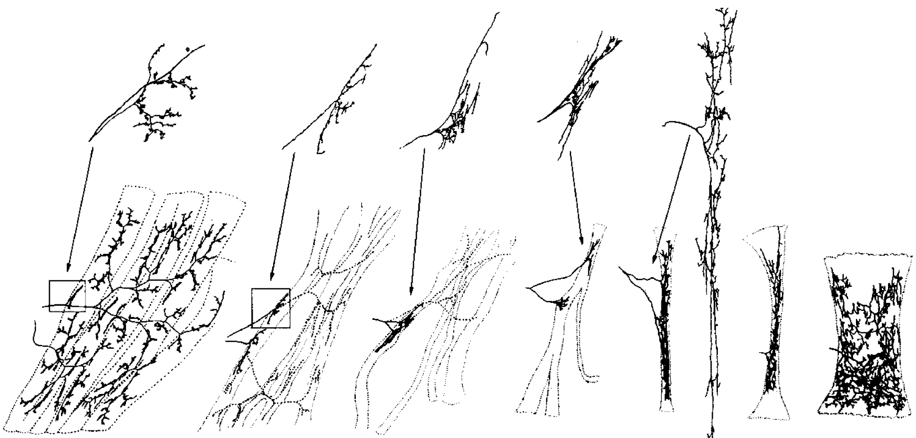

Figure 10 *Camera lucida* drawings showing the remodeling of the axonal arbor of motoneuron MN-12 through the pupal–adult transition (indicated as percentage of development) of *Manduca sexta*. The target muscle and its remains are shown in dotted outline. The arbor in the boxed area is shown at higher magnification above. Between 5 and 15% of development, the axonal arbor undergoes a massive collapse, leaving only two attachment sites on the remains of the first muscle fiber. These contact sites grow in size and complexity through 30% and then rapidly extend and branch over the proliferating muscle. Adult muscle differentiation and adult endplates are then elaborated between 60 and 95% of development. (Data from Truman, J.W., Reiss, S.E., **1995**. Neuromuscular metamorphosis in the moth *Manduca sexta*: hormonal regulation of synapses loss and remodeling. *J. Neurosci. 15*, 4815–4826; © by the Society for Neuroscience.)

Reiss, 1995). The concentration of steroid provided, though, is critical, as demonstrated by injecting pupae with a high dose of 20E early in adult development, thereby mimicking the rise in 20E that occurs on day P + 8. The early 20E causes the premature extension of the axonal arbor over its muscle target (Truman and Riddiford, 2002). Hence, E or low levels of 20E are associated with growth zone organization, whereas high levels of 20E shift the neuron into branch extension and scaffold formation.

A number of *in vitro* studies with isolated, identified neurons show that neurite outgrowth is a cell-autonomous response that can be elicited by 20E (review: Levine and Weeks, 1996). The earliest study utilized *Manduca* leg motoneurons (Prugh *et al.*, 1992), which were labeled *in vivo* by injecting a retrograde tracer into the leg of the caterpillar. Thoracic ganglia were then dissociated and the leg motoneurons grown in low density cultures. In the absence of 20E, these motoneurons extended an axon and showed long-term survival. When cultured with 1 μg 20E ml^{-1}, however, they showed extensive branching growth that mimicked their response to 20E *in vivo*. The 20E treatment had a striking effect on the form and the cytoskeletal composition of the growth cones of these neurons (Matheson and Levine, 1999). Growth cones from 20E-exposed neurons were larger and had an increased number of microtubule-based branches, presumably leading to enhanced formation and retention of higher order branches. Interestingly, if the same neurons were explanted from larval rather than pupal nervous systems, they showed no sprouting but a slight reduction in branching when challenged with steroid. Therefore, the stage specificity of the nature of the response that the cell shows *in vivo*, in terms of steroid-induced pruning versus sprouting, is preserved when the neurons are treated in isolation.

Most *in vitro* studies of identified neurons in both *Manduca* and *Drosophila* (e.g., Prugh *et al.*, 1992; Kraft *et al.*, 1998; Matheson and Levine, 1999) have used a concentration of 20E of 1 μg ml^{-1}. The study by McGraw *et al.* (1998), though, examined the role of different concentrations of 20E on the pattern of neurite outgrowth from identified neurosecretory cells (**Figure 11**). 20E levels in the 100 ng ml^{-1} range were ineffective in supporting the growth of secondary and tertiary branches, and concentrations over 1 μg ml^{-1} were needed for this higher-order branching. Interestingly, the neurons grew the most elaborate arbors if they were first exposed to 100 ng ml^{-1} for 5 days before the shift to the high steroid concentration. Possibly, the low dosage of steroid was having an effect similar to growth zone organization seen *in vivo*, which then resulted in a more extensive arbor, when the cell was shifted to the high hormone conditions.

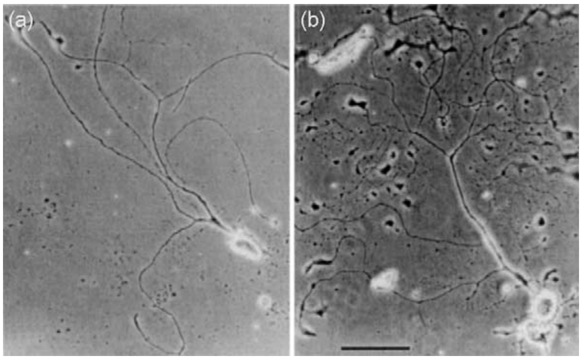

Figure 11 Photomicrographs of single lateral neurosecretory cells (LNCs) *in vitro*. (a) A single LNC in culture exposed to 100 ng 20E ml^{-1} for the entire 10-day period of growth. (b) A single LNC exposed to 100 ng 20E ml^{-1} for the first 5 days *in vitro* and then shifted to 1.5 μg 20E ml^{-1} for days 6–10. (From McGraw, H.F., Prier, K.R.S., Wiley, J.C., Tublitz, N.J., **1998**. Steroid-regulated morphological plasticity in a set of identified peptidergic neurons in the moth, *Manduca sexta*. *J. Exp. Biol. 201*, 2981–2992.)

The ecdysteroid requirements for the last phase, that of synaptogenesis, have not been examined. As with other events that occur during the latter half of adult differentiation (Schwartz and Truman, 1983), it is likely that the withdrawal of 20E may be essential for these events to go to completion.

JH is notable during the outgrowth phase only by its absence. In *Manduca*, the experimental application of JH mimics prior to the ecdysteroid rise results in a severe suppression of outgrowth, and neurons remain in a stunted, pupal-like form (Truman and Reiss, 1995). This ability of early JH treatment to suppress adult differentiation of these motoneurons is not surprising and is consistent with JH causing the repetition of a pupal molt. The more intriguing results are seen with later applications of JH after the neuron has been committed to its adult differentiation. For *Manduca* motoneurons, late treatment with JH has a quantitative effect and results in neurons with reduced adult arbors. The manner by which JH exerts quantitative control over arbor growth is discussed for the remodeling of sensory neurons in Section 2.4.8.2.

One question concerning the quantitative effects of JH on neuronal form is whether the effect of JH is directly on the neuron or indirect through effects on its targets. This is especially pertinent for the motor arbors, since the JH treatments reduce the size of both the target muscle and the arbor of the neuron that grows over it. Local application

of JH in *Manduca*, though, showed that local treatment to the muscle caused the expected reduction of muscle growth but did not suppress the normal elaboration of the motoneuron's axonal arbor (Truman and Reiss, 1995). Hence, the reduced arbor size seen after systemic treatment with JH is likely due to a direct action on the neuron itself.

2.4.7.3. Differentiation of Adult-Specific Neurons

2.4.7.3.1. Differentiation of arrested interneurons At the outset of metamorphosis, the larva possesses two classes of arrested interneurons: a small number of neurons born during embryogenesis and a much larger set born later during larval growth. Studies on tangential visual interneurons in *Drosophila* suggest that these two sets of neurons may differ in their developmental time-tables during metamorphosis (Taghert *et al.*, 2000). The OL2-A and OL3 classes of visual interneurons express the neuropeptide dFMRFamide in the adult. The large OL2-A neurons are born during embryogenesis and already show some morphological differentiation at the start of metamorphosis. Based on a *dFMRFa* reporter, the OL2-A neurons start transcribing the *dFMRFa* gene at the beginning of metamorphosis and start expressing the dFMRFamide peptide soon thereafter. The numerous OL3 neurons are generated postembryonically. They begin transcribing the *dFMRFa* gene slightly later than the OL2-A neurons but delay peptide expression until just before adult ecdysis. At this time, it is not known if the OL neurons present a unique case or if this difference in developmental trajectory is consistent for adult-specific neurons that have embryonic versus postembryonic origins.

Studies in *Manduca* have examined the hormonal requirements needed to initiate differentiation of the arrested imaginal neurons (Booker and Truman, 1987b). Resumption of development occurs during wandering, as the neurons show enlargement of their somata and dendritic and axonal sprouts appear (e.g., **Figure 4**). The *Manduca* studies focus on the abdominal lineages and deal only with cell survival and soma size. In the days following wandering, some of the immature neurons within a cluster degenerate, while others show soma enlargement. When larval abdomens were isolated either before (day $5+2$) or after (W 0) the wandering pulse of ecdysteroids, both neuronal loss and soma growth were prevented. Infusion of 20E into such abdomens restored the normal pattern of cell loss and soma growth. The effect of JH treatment on cell loss was complex, but treatment with a JH mimic suppressed the growth-promoting effects of 20E, irrespective of whether it was given before or after the wandering peak of ecdysteroids. Therefore, unlike remodeling larval neurons, these adult-specific neurons do not show "commitment" in response to the wandering peak of ecdysteroids. Their early outgrowth is responsive to the JH that normally appears during the prepupal peak. This action of JH may prevent these neurons from showing precocious outgrowth in response to the prepupal peak of ecdysteroids.

2.4.7.3.2. Visual interneurons of the optic lobes Although the majority of postembryonic neurons likely deal with new adult sensory information, the sensory neurons play no role in their production. Indeed, neurogenesis in the CNS is completed well before sensory axons reach the CNS. An exception to this generalization, though, occurs in the developing visual system. Rows of ommatidia are added progressively from the posterior to the anterior margin of the eye disc, and the outer layers of the optic lobe, the lamina and medulla, undergo a similar sequential production of visual interneurons. Neuroblasts in an outer proliferation zone (OPZ) generate the neurons for both of these regions. In early larval stages, symmetrical cell divisions within the OPZ expand the population of NBs. In the last larval stage, though, the NBs switch to asymmetrical divisions that produce GMCs, which then make neurons. In *Manduca*, this shift to neurogenesis requires the decline in JH (Monsma and Booker, 1996), and medulla neurons start being born early in the last larval stage. Lamina neurons, however, only appear after wandering, as the the first retinal afferents reach the optic lobe. In both *Manduca* (Monsma and Booker, 1996) and *Drosophila* (Selleck *et al.*, 1992), removal of the afferents prevents the birth of lamina neurons, although medulla neurons continue to be made. Studies on *Drosophila* show that the lamina GMCs undergo a G1 arrest and degenerate, unless they are contacted by the afferent axons, which supply Hedgehog, which drives them through the G1 blockage (Huang and Kunes, 1996).

The birth of lamina neurons has a unique requirement for afferent axons, but all regions of the optic lobe are sensitive to ecdysteroids. The ecdysteroid requirement is absolute in *Manduca* (Champlin and Truman, 1998a). In the absence of E or 20E, the cells in the outer proliferation zone arrest in the G2 phase of the cell cycle. A pulse of 20E, as short as 1.5–2 h, is sufficient to remove the block and send cells into mitosis, but they then arrest at the next G2 phase if no steroid is present. Therefore, during each cell cycle there is a single checkpoint, when steroid concentrations are assessed, and sustained proliferation therefore requires the tonic presence of E or a moderate level of 20E. The control point

is likely the transcription of the *Manduca* homolog of *string/cdc2 phosphatase*. This gene is a prominent regulator of the transition from G2 to M phase (Edgar and O'Farrell, 1989). In G2-arrested neuroblasts *string* transcription is directly and rapidly induced by exposure to 20E (D. Champlin and J.W. Truman, unpublished data).

Besides acting via transcriptional control, ecdysteroids also influence neurogenesis through a rapid response pathway that likely does not involve the nucleus. The neuroblasts in the OPZ respond to threshold 20E concentrations in an all-or-none fashion – either all of the cells are cycling or none of them (**Figure 12a**; Champlin and Truman, 2000). This all-or-none coordination within a lobe is mediated through local suppression of proliferation caused by nitric oxide (NO). Inhibitors of NO production, such as L-NAME, abolish this coordination and lower the levels of steroid needed to drive proliferation. Under these conditions, though, one now sees a graded response to the concentration of ecdysteroids (**Figure 12b** and **c**). The source of NO in the OPZ appears to be the NBs themselves. Treatment with moderate levels of 20E suppresses NO production within 15 min and is independent of RNA synthesis. The effect of NO appears to be downstream of *string* transcription because treatment with 20E in the presence of NO results in the rapid induction of *string* transcripts but the NBs still remain blocked in G2 (D. Champlin and J.W. Truman, unpublished data). Hence, 20E provides a stimulatory signal to NBs to promote neurogenesis and also acts to remove a local inhibition from the neighboring NBs. While ecdysteroids promote neurogenesis at moderate concentrations in *Manduca*, high levels of 20E terminate neurogenesis by causing the death of the NBs (Champlin and Truman, 1998a).

Drosophila differs from *Manduca* in that there is not an absolute requirement for E or 20E to support neurogenesis in the OL. Moderate levels of 20E do enhance proliferation and, as in *Manduca*, high levels of 20E terminate it. In the absence of 20E, neurogenesis is extended beyond its normal time and the brain overproduces optic lobe neurons (T. Awad and J.W. Truman, unpublished data).

2.4.8. Metamorphosis of the Sensory System

The transformation from a sedentary larva to an active, flying adult requires a profound change in how the insect senses its world. Most of the larval sensory system is directed towards proximal stimuli,

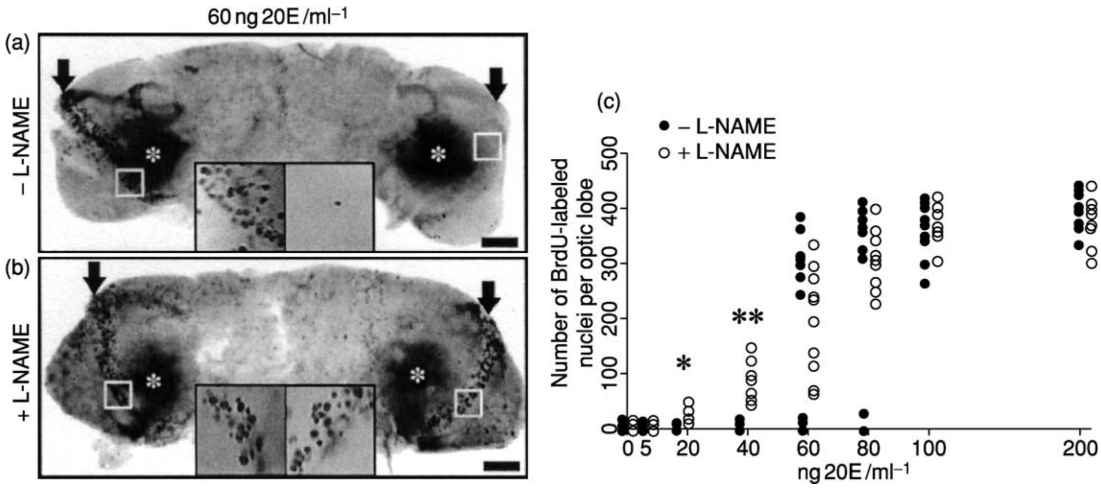

Figure 12 Ecdysteroid-dependent proliferation in the presence and absence of an inhibitor of nitric oxide synthase (NOS). Brains were collected 1 day after pupal ecdysis, desheathed, and cultured for 24 h in various concentrations of 20E. They were then pulsed with Bromodeoxyuridine (BrdU) for 2 h, and the number of cells incorporating BudR was then determined by immunocytochemistry. (a, b) Photomicrographs of brains cultured with 60 ng 20E ml^{-1}. In (b) 1 mM L-NAME was included from the start of the culture. BudR-labeled nuclei are black; arrows point to the outer proliferation zone. ∗ show pigment spots present in each optic lobe. The insets are higher magnification views of the boxed areas in each optic lobe. The brain in (a) illustrates the all-or-none character of the proliferation response seen at threshold concentrations of 20E, with one hemisphere inactive while the other is in full proliferation. With the NOS inhibitor (b), both lobes show similar, moderate levels of proliferation to the same concentration of 20E. (c) The number of cells that labeled with BudR after various treatments. Each point is from a single optic lobe incubated at the indicated 20E concentration with or without L-NAME. The low concentration data sets differ by ∗, $P < 0.05$, and ∗∗, $P < 0.005$. (Data from Champlin, D.T., Truman, J.W., **2000**. Ecdysteroid coordinates optic lobe neurogenesis via a nitric oxide signaling pathway. *Development 127*, 3543–3551.)

depending heavily on mechanoreception and having poorly developed visual and olfactory capacities. The adult has elaborate antennae and compound eyes, adapted for perceiving stimuli at distances, and batteries of new external sense organs associated with the adult legs, wings, and genitalia. The extent of carryover of larval sensory receptors into the adult stage varies. In *Drosophila*, all of the larval external sensory neurons degenerate, and adult external sensory neurons arise during the differentiation of imaginal discs and histoblast nests. The few larval sensory neurons that persist through metamorphosis are proprioceptors and some of the da sensory neurons. The axons from these persisting cells provide pathways that are utilized by the axons from adult-specific neurons, as they navigate towards the CNS (Usui-Ishihara *et al*., 2000; Williams and Shepherd, 2002).

In contrast to *Drosophila, Manduca* shows a greater percentage of larval sensory neurons that are carried through metamorphosis. The transition between the larval and adult sensory systems has been best described for the thoracic legs. As the larval leg undergoes degeneration and replacement by the adult leg, most of the larval sensory neurons degenerate but some of the neurons that supplied the external sensilla and the chorditonal organs persist through metamorphosis (Consoulas, 2000). Of special interest are the neurons of larval femoral chordotonal organ. While about half of the original 13 neurons that supplied the larval organ degenerate, the remainder serve to organize the adult structure. They are joined by 45–60 new neurons to make up the chorditonal organs of the adult leg (Consoulas *et al*., 2000b). While most studies of the hormonal control over the metamorphosis of the peripheral nervous system have focused on differentiation of adult-specific neurons, there is some information on remodeling sensory systems.

2.4.8.1. Remodeling of Larval Neurons: Pupal-Specific Modifications

The pupa stage has little behavioral relevance for the vast majority of central neurons, but this is not true for the sensory system. Pupae display some specialized behaviors, and a small set of peripheral and central neurons are dedicated to maintain these behaviors as the rest of the nervous system undergoes its metamorphic upheaval. In *Manduca*, these pupal-specific behaviors include abdominal respiratory movements and a pupal-specific defensive reflex, the gin-trap reflex. The neural basis of the latter is best understood (Bate, 1973).

Abdominal segments A4 to A6 of the pupa bear sharp-sided cuticular cavities, the gin traps, that protect the pupa from small soil arthropods. Stimulation of the sensory hairs in the trap excites an intersegmental interneuron that then excites the motoneurons to the ipsilateral, internal longitudinal muscles causing the rapid closure of the trap, crushing whatever is inside. The sensory hairs within the gin trap are recruited from the larval sensory hairs along the anterior border of the segment. In their transition to their pupal state, the hairs acquire a new morphology, and the sensory neurons expand their axonal projections within the CNS (**Figure 13**).

The studies on the metamorphosis of the gin-trap system was the first use of JH-induced mosaics to dissect developmental interactions within the CNS (Levine *et al*., 1986). Local application of JH to larval epidermis, fated to form the gin-trap, resulted in larval cuticle being deposited in that region ,while the remainder of the animal became pupal. A normal gin-trap formed on the control side, and its sensory neurons showed their normal axonal expansion and could drive the pupal reflex (**Figure 13a**). On the treated side, by contrast, the projection pattern of the sensory neurons remained larval, and stimulation of the cells could not evoke the closure reflex.

The pupal-specific sprouting of the sensory neuron requires both an exposure to 20E as well as the absence of JH. The 20E requirement was shown by permanently arresting the development of the larval abdomen by ligating the abdomen after the wandering stage. Under these conditions, the neurons destined for the gin trap permanently retain their larval morphology. Topical application of 20E in undecane to the presumptive gin trap region caused a local pupal molt in the underlying cells, while the remainder of the abdomen, including the CNS, remained arrested. The gin-trap sensory neurons showed their pupal sprouting, despite doing so in a CNS that was permanently larval (**Figure 13b**; Levine, 1989). These pupal neurons, though, could not initiate a gin-trap reflex, presumably because the interneuron involved in the reflex still was in its larval form. Together, these two sets of experiments show that the growth of the sensory arbor is not induced by the state of the CNS, but rather depends on the hormonal conditions experienced in the periphery, where the cell body resides.

2.4.8.2. Adult-Specific Remodeling of Sensory Neurons

The da sensory neurons extend complex dendritic arbors over the epidermis of the larva. At metamorphosis neurons like ddaE have their dendrites severely pruned back, the cell bodies migrate dorsally and then elaborate new dendritic trees (Williams and Truman, 2004). During their remodeling, these

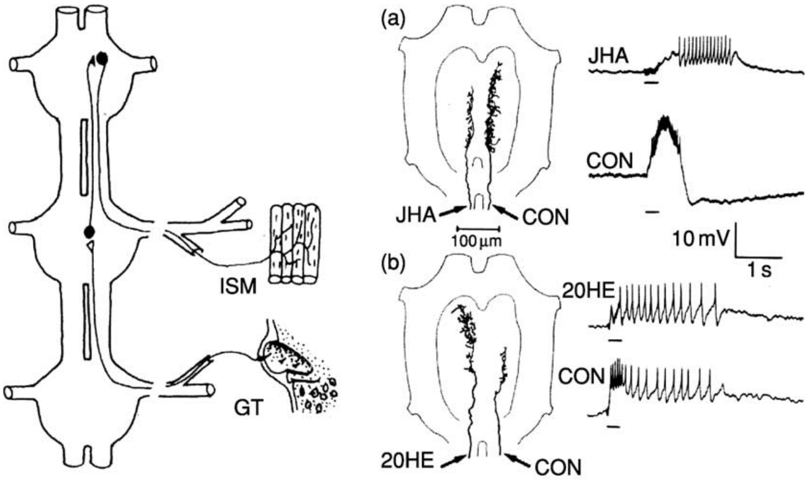

Figure 13 Hormonal control over the larval–pupal tranformation of the gin-trap system. (Left) Drawing showing the relationship between the sensory hairs in the gin-trap (GT) and the motoneurons to intersegmental muscles (ISM) that mediate the trap closure. (Right) Motoneuron responses to stimulation of the trap sensory neurons in heterochronic mosaic animals. (a) The A4 ganglion from a mosaic pupa, in which the presumptive gin-trap region of the left fifth segment was treated topically with a JH mimic. The drawing shows that single sensory neurons from the JH treated region retained their sparse larval arbors, whereas the neuron from the control side grew the expanded terminal arbor characteristic of the pupal stage. To the right of the drawing are shown the responses of ipsilateral, pupal ISM motoneurons to stimulation of treated and control sensory neurons. The control neurons evoked the abrupt excitation characteristic of the closure response, whereas the treated neurons evoked a low-level, sustained, larval-like response. (b) The A4 ganglion from a mosaic larva. After abdominal ligation early in the 5th larval stage, the presumptive gin-trap region on one side of the fifth segment was treated with 20E. The contralateral control neurons maintained their larval pattern of branching but the 20E-treated cells grew pupal-like arbors. In both cases, however, the stimulation of the sensory neurons evoked larval-like responses from the ipsilateral motoneurons. ((Right) Data from Levine, R.B., Weeks, J.C., **1990**. Hormonally mediated changes in simple reflex circuits during metamorphosis in *Manduca*. *J. Neurobiol. 21*, 1022–1036.)

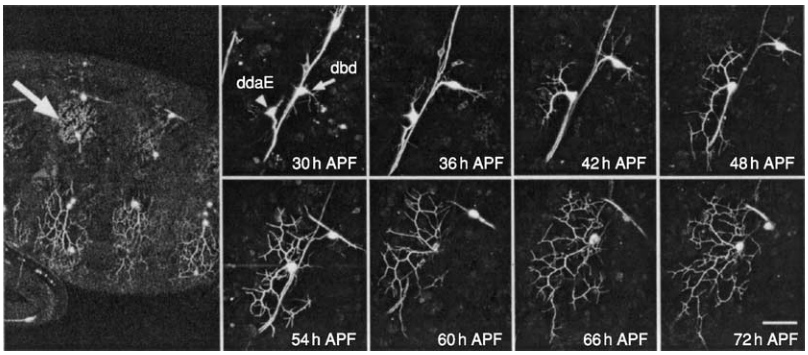

Figure 14 Adult outgrowth of the dendrites of the da sensory neuron ddaE. (Left) Low-power confocal image of the lateral aspect of the abdomen of a live developing adult of *Drosphila* at about 70 h APF (after puparium formation). The da neurons are expressing a membrane-targeted green fluorescent protein (GFP); arrow shows one of the segmentally-repeated ddaE's. (Right) Confocal images of the same set of neurons followed through metamorphosis from 32 to 72 h APF showing the time-course of adult dendrite outgrowth by ddaE. Dbd is a sensory neuron that produces a dorsal stretch receptor. (From Williams, D.W., Truman, J.W., **2004**. Mechanisms of dendritic elaboration of sensory neurons in *Drosophila*: insights from in vivo time-lapse. *J. Neurosci. 24*, 1541–1550; © by the Society for Neuroscience.)

sensory neurons progress through similar phases to those seen for central neurons, except that cell body migration occurs as new outgrowth zones are being established. Also, the dendrites of these primary sensory neurons do not receive synaptic inputs.

The growth of the adult dendrites by the da neurons occurs during the surge of 20E that causes adult differentiation. As evident from the time-lapse images in Figure 14, the dendrites show a rapid extension that is also accompanied by occasional branch retractions and the formation of interstitial branches. After the overall form and extent of the arbor is established, the tree then fills in with higher order twigs (Williams and Truman, 2004). The

manner by which 20E directs this outgrowth has not been examined, but the effects of JH are notable. As with other tissues in *Drosophila*, JH treatment does not suppress the larval–pupal transition of these cells – i.e., they prune back normally irrespective of the presence or absence of JH. JH treatment, though, does impair the adult outgrowth of these cells, and they remain in a pupal-like form. Time-lapse studies suggest that the failure of these JH-treated cells to extend branches may be due to the persistence of the strong retraction programs that were part of the pruning process (Williams and Truman, 2004). The effect of JH treatment on the maintenance of retraction programs is more evident for animals treated with JH mimics at about 24 h APF. As with late treatment of motoneurons (see Section 2.4.7.2.2), da sensory neurons in such animals grow an adult arbor but it is reduced in extent and complexity. These neurons show a normal outgrowth program as measured by the rate of birth of new dendritic branches. The retraction programs, however, are maintained beyond their normal time, thereby reducing the rate of branch extension and the number of branches that finally persist. The manner by which JH prevents the inactivation of retraction programs is unknown.

2.4.8.3. Control Over Birth of Adult Sensory Neurons

Studies with cultured wing imaginal discs from wandering larvae show that the 20E of the pupariation peak is required for the birth of the sensory neurons on the anterior margin of the wing of *Drosophila*. The effect of this hormone, though, is to relieve a repression imposed by the ecdysone receptor complex (Schubiger and Truman, 2000). This relationship first became evident from experiments, in which clones lacking Usp were induced in wing imaginal discs (Schubiger and Truman, 2000). Neuronal birth and axonal outgrowth occurred earlier within such clones as compared to surrounding, wild-type tissues. Similar advancement in development with the lack Usp was also seen for the ecdysone-dependent movement of the morphogenetic furrow in the eye disc (Zelhof *et al*., 1997; Ghbeish *et al*., 2001). Importantly, when wing discs containing such clones were transferred into culture lacking 20E, they showed the expected arrested development except for the patches that lacked Usp. The latter cells progressed into neurogenesis and axonal outgrowth despite the lack of steroid (**Figure 15**). More recent experiments using RNAi techniques to remove EcR (Roignant *et al*., 2003) similarly showed that the lack of EcR also brings about the precocious

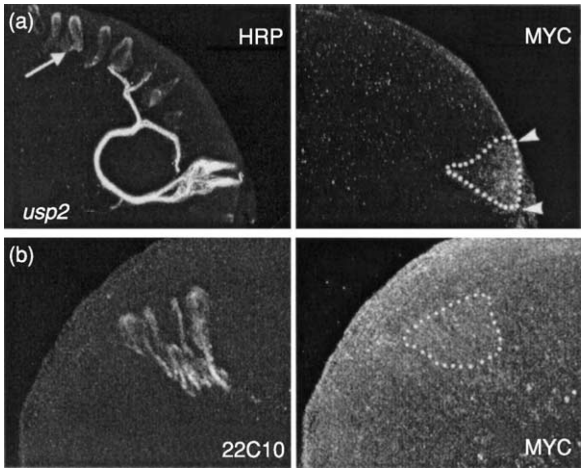

Figure 15 The effect of the lack of Usp on the early birth and differentiation of sensory neurons in the wing disc of *Drosophila*. The wing discs bore clonal patches of tissue that lacked a functional *usp* gene and were marked by expression of the MYC protein (right, enclosed by dotted area). Neuronal differentiation was determined by immunostaining for a horseradish peroxidase (HRP) epitope or with the monoclonal antibody 22C10 (left). (a) *In vivo* at pupariation, the sensory neurons along the anterior wing margin (arrow) are just beginning axonal outgrowth and expression of the HRP epitope, but within the *usp* null clone the neurons are well advanced in their development with extensive axonal outgrowth. (b) Wing discs from early wandering larvae that were maintained *in vitro* in the absence of 20E. Metamorphic development failed to occur in the wild-type tissue, but cells within the *usp* null clone showed normal neurogenesis and axonal outgrowth despite the lack of steroid. (Data from Schubiger, M., Truman, J.W., **2000**. The RXR-ortholog Usp suppresses early metamorphic processes in the absence of ecdysteroids. *Development 127*, 1151–1159.)

birth and axonal outgrowth by wing sensory neurons (M. Schubiger and J.W. Truman, unpublished data). Consequently, in the imaginal discs, the EcR/Usp complex functions as a potent repressor of genes involved in the selection and differentiation of sensory neurons. The major role of ecdysteroids is to relieve this repression, thereby allowing development to progress.

Although ecdysteroids are clearly involved in controlling the birth of adult sensory neurons, relatively little is known about how the steroid titer impacts their subsequent differentiation. One case in which we have some insights, though, is in the development of chemosensory sensilla on the antenna of *M. sexta* (Vogt *et al*., 1993; see **Chapters 1.12** and **3.15**). The final maturation of the chemosensory sensilla occurs during the last 10% of adult development with the appearance of odorant binding proteins (OBPs) and odorant degrading enzymes. In cultured antennae, OBP expression could be induced prematurely if 20E was absent from the culture medium. The addition of 20E then

blocked the premature expression of the OBPs. Hence, declining levels of ecdysteroid may have an important function in coordinating the terminal maturation of the sensory organs.

2.4.8.4. Sensory Systems: The Compound Eye

The building of the compound eye is one of the spectacular achievements of metamorphosis. The organization of the eye imaginal disc begins at the posterior border of the disc and progresses anteriorly as the morphogenetic furrow moves across the disc. In *Manduca* the hormonal control over the organization of the eye disc is relatively simple because the establishment of the furrow occurs after wandering, when metamorphosis has commenced. In *Drosophila*, by contrast, the establishment and early movement of the furrow is advanced to the middle of the last larval stage. The role of hormones in controlling this early patterning of the disc is unclear, but once wandering has begun, the furrow movement then appears to require ecdysteroids (Brennan *et al*., 2001).

The analysis of the role of ecdysteroids in the formation and patterning of the compound eye is most detailed for *Manduca* (**Figure 16**; Champlin and Truman, 1998a). In this insect, the eye imaginal disc does not form until well into the last larval stage. The earlier larval instars have a crescent-shaped eye primordium immediately anterior of the stemmata, but during the larval molts these cells make head capsule cuticle, as do their neighbors. Their developmental potential becomes apparent early in the last larval stage, when they enlarge, detach from the overlying cuticle, and begin proliferating to form the eye imaginal disc. The growing disc rapidly enlarges until the time of wandering, at which time it becomes dependent on ecdysteroid to support further proliferation. The divisions in this latter phase are directed towards the patterning of the eye disc and support the movement of a morphogenetic furrow. In the wake of the furrow, cells differentiate into the photoreceptors and the cone and pigment cells that comprise the ommatidia. The progression of the furrow begins the day after wandering and is completed about 10 days later, well into adult differentiation.

In vitro experiments show that both E and 20E support proliferation and movement of the furrow (Champlin and Truman, 1998b). The levels of

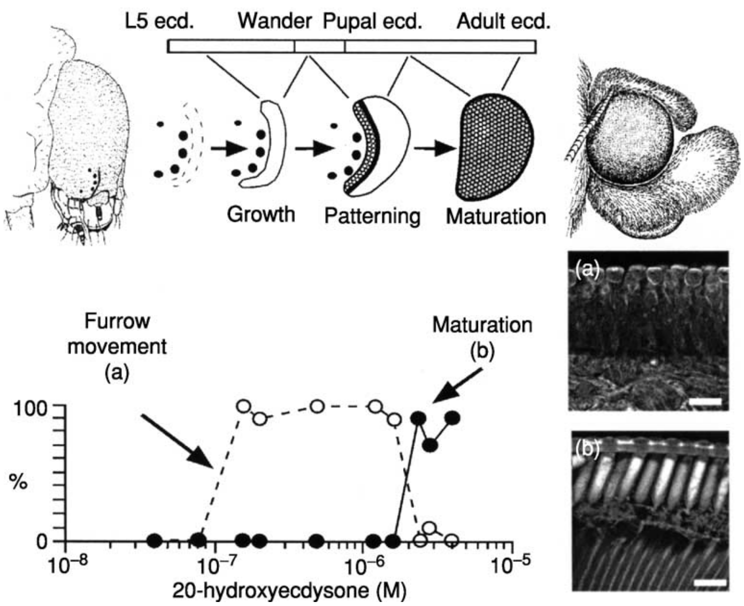

Figure 16 Eye development in *Manduca sexta*. (Top) Time-line of development: at the start of the last larval stage, the crescent-shaped eye primordium (dashed line) lies just anterior to the larval stemmata. These cells detach and begin proliferating by 2 days into the last instar and form the eye imaginal disc. After the larva stops feeding and begins the wandering stage, low levels of ecdysteroid support the movement of the morphogenetic furrow to organize the ommatidia units that then mature in response to high levels of 20E. (Bottom) Summary of the response of the pupal eye imaginal discs to treatment with 20E *in vitro*. (Left) The dose–response relationship showing the 20E concentrations needed to evoke mitosis and movement of the morphogenetic furrow (open circles), and the cellular maturation of the ommatidial units (filled circles). (Right) Confocal optical sections of the region posterior to the furrow. In response to low levels of 20E (a), the ommatidial cell types differentiate and organize into ommatidial clusters. High concentrations of 20E (b) induce terminal maturation as manifest by the synthesis of the screening pigments, cuticular lens, crystalline cones, and elongated rhabdomeres. Scale bars = 25 μm. (Data from Champlin, D.T., Truman, J.W., **1998b**. Ecdysteroids govern two phases of eye development during metamorphosis of the moth, *Manduca sexta*. *Development 125*, 2009–2018.)

20E needed to support proliferation are lower than E, but the latter levels are still in the physiological range seen during early adult differentiation (Warren and Gilbert, 1986). As discussed for the optic lobes above (see Section 2.4.7.3.2), proliferation and patterning of the eye disc requires the tonic presence of steroid but levels must be maintained in a range between 60 and 1000 ng 20E ml^{-1}. Levels above 1000 ng ml^{-1} permanently suppress proliferation and furrow movement and cause the cells behind the furrow to undergo maturation and make rhabdoms, crystalline cones, screening pigments etc. (**Figure 16**). The eye disc cells in front of the furrow, by contrast, are undetermined and are induced to make a naked, adult cuticle (Champlin and Truman, 1998b). The exposure to high levels of 20E initiates a differentiative program that can continue even if the steroid is subsequently withdrawn.

Once the imaginal disc has started ecdysteroid-dependent patterning, the tissue can be shifted into the terminal differentiation at any time by raising the 20E titer above 1000 ng ml^{-1}. Hence, if high levels of 20E are experimentally supplied precociously, then a miniature eye forms (Champlin and Truman, 1998b). One complication with this relationship is that the patterning eye disc is actually exposed to levels of 20E above 1000 ng ml^{-1} twice; first during the larval pupal transformation and then at about day 8 of adult development. Importantly, though, JH is also present during this first exposure to high levels of 20E. If JH is experimentally removed by allatectomy of the larva, then the high 20E levels of the larval–pupal molt do indeed promote early eye differentiation, and the pupa forms with a miniature adult eye (Kiguchi and Riddiford, 1978; Champlin and Truman, 1998b). *In vitro* experiments on the differentiation of the ventral diaphragm muscle in *Manduca* show that JH does not interfere with responses to moderate levels of 20E but suppresses the new responses that occur when shifting to high levels of 20E (Champlin *et al.*, 1999).

Experiments, in which Usp function was removed from the patches of cells in the eye imaginal disc of *Drosophila*, also illustrate the complex control of the differentiation of this structure (Zelhof *et al.*, 1997; Ghbeish *et al.*, 2001). In clones of cells that lack *usp*, the furrow shows an advancement over that seen in surrounding wild-type tissue. This result is similar to that seen for the wing sensory neurons (see Section 2.4.8.3) and argues that ecdysteroids regulate furrow progression by removing the repression imposed by EcR/Usp. Later on, Usp also has a role in hormone-dependent activation (Ghbeish *et al.*, 2001).

2.4.9. Steroid Receptors and the Coordination of the Metamorphic Development

2.4.9.1. Relationship of Receptor Expression and Cellular Responses

Indications that steroid receptor levels vary through time in the CNS came with autoradiogarphic studies of the binding of radiolabeled ponasterone. Bidmon *et al.* (1991) reported that very few brain neurons showed ponasterone accumulation early in the last larval stage but that the number increased dramatically shortly after wandering, and then declined as the ecdysteroid peak declined. Substantial ponasterone binding then reappeared after pupal ecdysis. The variation in ponasterone binding at certain times could be correlated with different steroid-dependent fates. For example, at the end of metamorphosis neurons fated to die showed much higher levels of ponasterone binding than did those that would persist in the adult stage (Fahrbach and Truman, 1989).

Studies of receptor distributions became easier with the identification of the EcR gene (Koelle *et al.*, 1991) and with the production of antibodies to detect the receptor protein. The story became complex, though, with the discovery that there were three isoforms of the receptor (Talbot *et al.*, 1993) and that these were expressed in a complex pattern through metamorphosis (**Figure 17**; Truman *et al.*, 1994; see **Chapter 3.5**). The expression patterns of only EcR-A and EcR-B1 are known in detail. That of EcR-B2 is generally assumed to be similar to EcR-B1, but this remains to be established. The pattern of EcR-B1 and -A expression mirrors the diverse origins and cellular fates of the neurons in the CNS. Little EcR expression is detected in neurons through the early larval instars. Also, when EcRs that carry dominant negative mutations (Cherbas *et al.*, 2003) are expressed in larval neurons, they produce no obvious effects on the morphology or functioning of the neurons (J.W. Truman, L. Cherbas, and P. Cherbas, unpublished data). This suggests that the ecdysteroid signaling pathway has little function in most larval neurons prior to metamorphosis.

Detectable EcR first appears in *Drosophila* neurons in the middle of the last larval instar in preparation for metamorphosis. As summarized in **Figures 9 and 17**, each of the phases in metamorphic remodeling of larval neurons is associated with a different combination of EcR isoforms. EcR-B1 is at its highest levels in larval neurons and in the γ-neurons of the mushroom bodies just before both sets of cells begin pruning back their larval processes (Truman *et al.*, 1994; Lee *et al.*, 2000). All other

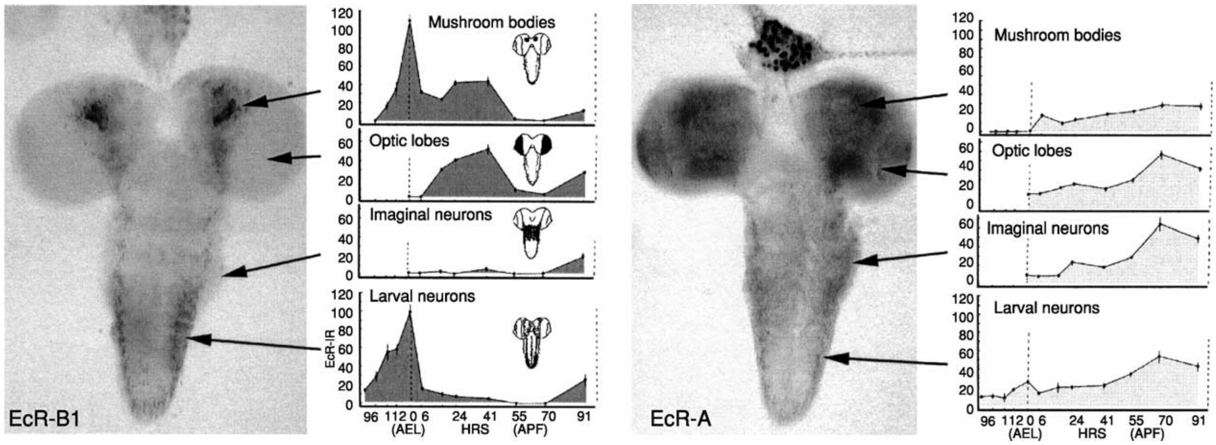

Figure 17 Temporal and spatial variation in the expression of the EcR-B1 (Left) and EcR-A (Right) through metamorphosis. The photomicrograph shows the distribution of both isoforms in the brain lobes and ventral nervous system at the time of puparium formation; the endocrine ring gland is located in front of the brain at the top of the picture. The graphs show the isoform-specific immunoreactivity in various types of neurons as determined by confocal microscopy. Major peaks of ecdysteroid occur at pupariation, and about 24–40 h after puparium formation (APF). Hours 96–112 AEL (after egg-laying) are during the 3rd larval instar. (Modified from Truman, J.W., Talbot, W.S., Fahrbach, S.E., Hogness, D.S., **1994**. Ecdysone receptor expression in the CNS correlates with stage-specific responses to ecdysteroids during *Drosophila* and *Manduca* development. *Development 120*, 219–234.)

postembryonically derived neurons, as well as the arrested embryonic neurons (J.W. Truman and D.D. Williams, unpublished data), lack this early EcR-B1 expression. The importance of the EcR-B isoforms to the pruning response was established using *Drosophila* mutants that lacked one or both of the EcR-B isoforms. Most larvae homozygous for such mutations die during larval life but a few survive to the start of metamorphosis (Bender *et al.*, 1998), at which time tissues within the larva desynchronize their development; the larval tissues arrest their development but imaginal tissues continue into metamorphosis. Within the CNS, arrested imaginal neurons begin adult differentiation, but larval neurons (Schubiger *et al.*, 1998) and the γ neurons of the mushroom bodies (Lee *et al.*, 2000) do not prune back their larval processes. Since EcR-B mutants show this early metamorphic arrest, it was possible that the lack of pruning was not the direct result of a lack of EcR-B in the neurons in question. Subsequent experiments expressed each of the EcR isoforms in specific neurons in arrested EcR-B mutants. Both axonal pruning in the mushroom body neurons (Lee *et al.*, 2000) and dendritic pruning in the Tv neurosecretory cells (Schubiger *et al.*, 2003) were induced in arrested mutant larvae, when EcR was expressed in the respective neurons. Importantly, EcR-A was relatively ineffective, EcR-B1 was moderately effective, and EcR-B2 was very effective in causing pruning of the larval branches (Figure 18). Hence, the proper receptor isoform(s) is essential for mediating the steroid-induced pruning of these cells. A question remains, though, as to whether the pruning decision is a "binary" one or whether variation in the levels of EcR-B isoforms determines how much of a neuron's arbor will be removed.

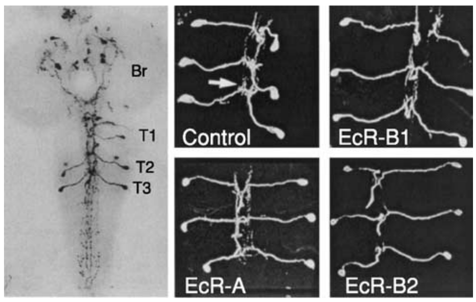

Figure 18 EcR isoform requirements for the pruning of dendritic arbors by the Tv neurosecretory neurons. (Left) Photomicrograph showing the immunostaining of the larval nervous system of *Drosophila* with an antibody against the molluscan neuropeptide SCP_B. The Tv neurosecretory cells in the thoracic neuromeres (T1, T2, T3) show prominent immunostaining (one cell of the Tv pair in T1 is missing). (Right) Confocal images showing the Tv neurons in an EcR-B mutant. The cells were visualized by using the UAS/GAL4 system to express a membrane directed GFP in only the Tv neurons. The fine dendrites at the midline (arrow) are the larval dendrites that fail to be removed in the mutant (Control). For the remaining examples, each of the indicated EcR isoforms was expressed in the Tv neurons in an EcR-B mutant background. Full pruning occurred with expression of the EcR-B2 isoform. (Data from Schubiger, M., Tomita, S., Sung, C., Robinow, S., Truman, J.W., **2003**. Isoform specific control of gene activity *in vivo* by the *Drosophila* ecdysone receptor. *Mech. Devel. 120*, 909–918.)

Pruning is the only phase of neuronal development in which EcR isoform requirements have been rigorously established by loss-of-function and gain-of-function experiments. Correlation of isoform

presence with other developmental phases, however, suggests that the EcR-B isoforms may have functions beyond pruning. For example, EcR-B1 persists in remodeling neurons as they organize their growth zone, but then disappears with the beginning of axon elongation and scaffold formation. Perhaps the presence of EcR-B during this phase maintains some branch retraction programs that help in organizing a growth zone, and also prevents the premature extension of the neuron to its final targets.

The neurons of the optic lobes are unique because they do not prune but they show prominent EcR-B1 expression. This expression begins relatively late, starting at 10 h APF, when the last wave of photoreceptor axons arrive in the OL, and lasting until about 45 h APF, when the gradients of development across the optic lobes are finally complete (Meinertzhagen and Hansen, 1993). This EcR-B1 expression in the OL may have a function similar to that proposed above for organization of the new growth zone in remodeling larval neurons, i.e., it may maintain the growth cones of the interneurons in a plastic state until all of neurons across the optic lobe have developed to the state that they can finalize their synaptic partners.

Both remodeling larval neurons and adult-specific neurons express only EcR-A at the time when they extend branches over their target or through the CNS. They all express EcR-B1, however, as they enter into the synaptogenesis phase. The functional roles of these receptor isoforms during this last phase have not been examined experimentally.

A striking aspect of EcR expression is seen in the neurons that will die at the end of metamorphosis. These neurons begin showing high levels of EcR-A early in adult differentiation (18 h APF) and these levels stay elevated until the neurons degenerate at 6–10 h after adult emergence (Robinow *et al.*, 1993). As described above (see Section 2.4.7.1.2), the disappearance of 20E at the end of metamorphosis is essential to induce *reaper* and to bring about cell death. Since the A/B region of EcR-A appears to have a repressive function (Mouillet *et al.*, 2001), it may be that the protein that represses *reaper* may be EcR-A itself. This repressive function would only be relieved when the steroid titers finally fell at the end of the molt.

2.4.9.2. Regulation of EcR Isoform Expression

EcR is a direct response gene and treatment with 20E enhances the production of EcR transcripts (see **Chapter 3.5**). At least at the start of metamorphosis, the B promoter appears more sensitive than the A promoter, so that rising steroid titers initially favor EcR-B1 expression but then switch to EcR-A when titers are high enough (e.g., Hiruma *et al.*, 1997). In the developing eye of *Manduca*, for example, levels of 20E that shift the eye from proliferation and patterning to final differentiation also causes a shift in expression from EcR-B1 to EcR-A (Champlin and Truman, 1998b).

The steroid regulation of EcR expression is likely shared by many tissues, but the selection of EcR-isoforms may also depend on cell–cell interactions. For example, in the remodeling musculature of *Manduca*, myoblasts at the site of nerve contact show EcR-B1 expression and elevated mitotic activity. Denervation of the remodeling muscle results in both the rapid loss of EcR-B expression and the suppression of proliferation (Hegstrom *et al.*, 1998). These results suggest that the neuron controls the selection of receptors expressed by the underlying myoblasts. Such interactions also take place in the CNS. Mutations in the TGF-β/activin receptor suppress pruning in the γ-neurons of the mushroom bodies and also blocks the appearance of EcR-B1 in these cells. Importantly, in mutant animals, the selective expression of EcR-B1 in the γ-neurons partially restores the ability of these cells to prune (Zheng *et al.*, 2003).

Acknowledgments

I am grateful to Darren Williams, Margrit Schubiger, Heather Brown, and Lynn Riddiford for many fruitful discussions during the preparation of this review. Unpublished results were from research supported by NIH (NS 13079 and NS 29971).

2.5 Programmed Cell Death in Insect Neuromuscular Systems during Metamorphosis

S E Fahrbach, Wake Forest University, Winston-Salem, NC, USA
J R Nambu and L M Schwartz, University of Massachusetts, Amherst, MA, USA

2.5.1. Introduction

Programmed cell death (PCD) is a fundamental component of the postembryonic development of the neuromuscular systems of holometabolous insects (see **Chapters 1.10–1.12**, **2.2**, and **2.3**). Nerve and muscle cells born during embryogenesis are deleted in a segment- and cell-specific fashion at both the larval–pupal and pupal–adult transitions. Although such deaths presumably occur in all insects with complete metamorphosis, almost all of the information on this topic has been obtained from the study of two species, the fruit fly *Drosophila melanogaster* and the tobacco hawkmoth *Manduca sexta*. The sophistication of the genetic tools available for manipulating and analyzing *Drosophila* has allowed many of the key regulatory events in cell death to be identified in this model. In addition, the success of large-scale genetic screens for embryonic pattern formation as well as detailed analysis of Hox gene clusters (see **Chapter 1.8**) has provided tremendous insight into the mechanisms underlying specification of cell populations, elaboration of body axes, and organogenesis. These insights into early development provide a strong base for our understanding of metamorphosis. The small size of fruit flies, however, limits the utility of *Drosophila* for physiological and biochemical studies involving hormone manipulations, tissue transplantation, and surgical interventions. The lepidopteran *M. sexta* is an alternative model that is uniquely suited for these sorts of experimental approaches and serves as the insect equivalent of the laboratory white rat (Fahrbach, 1997).

Most investigations have focused on the regulation of PCD by hormonal signals or the molecular mechanisms of developmental cell death (see

Chapter 2.4). In the first sections of this chapter, the history of this field is reviewed, and then an overview of the *Manduca* and *Drosophila* models is presented. The following sections describe the endocrine control of cell death, and the molecular, physiological, and genetic mechanisms that bring about the controlled loss of these cells. A final section presents unresolved issues. An unusual feature of this chapter will be the parallel presentation of information on neuronal and muscle death during metamorphosis. The aim of this chapter is to highlight the features of PCD common to both tissues without obscuring tissue-specific features.

2.5.2. PCD, Apoptosis, Autophagy, or Necrosis?

It is now widely recognized that cell death is a normal part of development in all multicellular and some single-celled organisms (Ameisen, 2002). The capacity to remove selected cells during development provides organisms with a plastic response to many developmental contingencies. In vertebrates, PCD has been demonstrated to:

1. Match the sizes of interacting populations of cells, such as oligodendrocytes, to the axons they myelinate (Barres *et al*., 1992).
2. Remove deleterious cells, such as self-reactive T cells (Smith *et al*., 1989).
3. Sculpt the body, such as in the loss of interdigital cells in the fetal hand (Zuzarte-Luis and Hurle, 2002).
4. Remove "obsolete" cells, such as the tail of the tadpole (Yoshizato, 1996).

In insects, the best-characterized examples of PCD take place not only during embryogenesis, but also during metamorphosis in holometabolous insects, when larval tissues are destroyed to allow the formation of new structures in the adult. PCD during insect development, therefore, provides specific examples of a widespread phenomenon rather than being unique to Arthropoda.

2.5.2.1. Apoptosis

In both vertebrates and insects, dying cells can display one of several distinct morphologies. The most widely displayed and best-characterized morphology associated with both developmental and pathological cell death is apoptosis, a term that was coined by Kerr, Currie, and Wyllie (Kerr *et al*., 1972). As introduced, apoptosis was a purely morphological description that implied neither an underlying mechanism nor a specific developmental context. During the process of apoptosis, cells shrink and display dramatic plasma membrane zeosis, during which numerous protuberances or "blebs" are formed. Time-lapse photographs of cells undergoing apoptosis in culture look like drops of water skittering on a hot skillet. Under normal conditions *in vivo*, these cells are rapidly phagocytosed either by neighboring cells or by macrophage-like phagocytes (Platt *et al*., 1998; Savill and Fadok, 2000; Fadok and Chimini, 2001; Henson *et al*., 2001; Franc, 2002; Geske *et al*., 2002).

The nucleus of apoptotic cells condenses, and the chromatin in these cells becomes electron dense and marginated along the inner aspect of the nuclear envelope. These morphological changes are the physical manifestation of a massive cleavage of genomic DNA that occurs when endogenous nucleases become activated and cleave the linker DNA between individual nucleosomes (Wyllie *et al*., 1984; Enari *et al*., 1998). The fragmentation of the genome can be visualized when DNA is extracted and fractionated by size in agarose (Eastman, 1995).

It is sometimes difficult to detect these "apoptotic ladders" because dying cells are usually intermingled with healthy ones. In addition, as tissues are homogenized during DNA isolation, it is impossible to determine which subpopulation of cells within a tissue contributed to the degraded DNA. An alternative strategy for detecting cells with fragmented genomic DNA is to employ *in situ* labeling techniques on tissue sections such as terminal deoxynucleotidyl transferase (TdT)-mediated dUTP-biotin nick end labeling, commonly referred to as the TUNEL method (Gavrieli *et al*., 1992; Ben-Sasson *et al*., 1995).

2.5.2.2. Autophagy

While apoptosis is the morphology that is most commonly observed during PCD, particularly during embryogenesis, it is not the only one. Other suicidal cell deaths are designated as autophagic or type II degeneration (Clarke, 1990; Nixon and Cataldo, 1993; Bursch, 2001). Cells undergoing autophagy lack, in general, an initial condensation of chromatin and are instead characterized by the formation of autophagic bodies within the cytoplasm. Unlike apoptosis, there are no definitive markers visible using light microscopy that define autophagic cell death. This has limited the analysis of autophagy during development.

2.5.2.3. PCD is an Inclusive Term

The term PCD encompasses both apoptotic and autophagic cell deaths that occur as a normal part of development. The term PCD is used in this

chapter, unless the death of a uniquely identifiable cell at a particular developmental stage has been clearly defined as being either apoptotic or autophagic based on ultrastructural criteria. The distinction is more than semantic, as the evidence argues strongly that there are multiple molecular mechanisms of nonpathological cell deaths (Schwartz *et al.*, 1993; Bursch *et al.*, 2000; Jones and Schwartz, 2001; Thummel, 2001). Occasional confusion has arisen in the literature because autophagy and apoptosis can sometimes share features, such as caspase activation and positive TUNEL staining (Ben-Sasson *et al.*, 1995; Kinch *et al.*, 2003); also, relatively few studies have investigated the ultrastructure of dying insect cells, which is required for the detection of autophagic bodies.

2.5.2.4. Necrosis

While apoptosis and autophagy are carefully orchestrated developmental decisions, all cells can be induced to die by necrosis, a passive form of cell death that occurs in the absence of normal physiological responses. Necrosis can be induced in any cell following external insult such as heat, salt, abrasion, toxin exposure, etc. (Dive *et al.*, 1992; Kroemer *et al.*, 1998). Necrosis typically follows direct or indirect disruption of plasma membrane integrity, which in turn results in an influx of ions and water and subsequent cell swelling and lysis. In vertebrates, which have an adaptive immune response, necrosis provides a valuable warning to the immune system that focal injury has occurred, because the cellular constituents that are liberated during necrosis are highly inflammatory (MacDonald and Stoodley, 1998; Fadok *et al.*, 2001). In fact, endogenous responses to necrosis are responsible for much of the secondary tissue damage that accompanies injury.

2.5.3. Historical Overview and Current Trends

The first morphological description of PCD during insect metamorphosis of which we are aware was a description of the death of intersegmental muscles (ISMs) provided in 1936 by Kuwana working with the silkmoth *Bombyx mori* (Kuwana, 1936). The phenomenon of ISM death was largely unknown in the West, until it was independently described by Finlayson (1956). With the exception of a modest number of descriptive papers documenting examples of cell death in other insect taxa, little was published about cell loss during arthropod development for most of the subsequent decade. (A compendium of the early studies of cell death in insects can be found in Glücksmann's (1951) famous but now largely forgotten review of the field of cell death.) A multifaceted analysis of PCD based on analysis of the ISMs was initiated in the mid-1960s by Richard Lockshin and Caroll Williams (Lockshin and Williams, 1964, 1965a, 1965b, 1965c). In fact, it was in these early reports that the term "programmed cell death" was first introduced into the literature (Lockshin, 1963).

The first detailed description of neuronal death during insect metamorphosis, published in 1974, was a description of the postembryonic changes in neuronal populations observed in the abdominal ganglia of *M. sexta* (Taylor and Truman, 1974). James Truman and his colleagues exploited their ability to count the motoneurons in individual ganglia by backfilling the cut ends of peripheral nerves with cobalt; they reported that motoneurons were lost from the abdominal ganglia at both the larval–pupal and pupal–adult transitions. Many of these motoneurons were later identified as specific individuals, permitting the precisely regulated nature of metamorphic neuron death to be established (Truman, 1983; Levine and Truman, 1985).

Studies by Schwartz and Truman subsequently demonstrated that the changes associated with ISM development and death in *Manduca* at the end of metamorphosis are controlled by hormonal signals, particularly by the steroid hormone 20-hydroxyecdysone (20E) (Schwartz and Truman, 1982, 1983) (see **Chapter 2.4**). This principle of steroid control of nerve and muscle fate at the metamorphic transitions was extended to the death of abdominal neurons that occurs after adult eclosion in *Manduca* (Truman and Schwartz, 1984) and to the death of *Manduca* proleg motoneurons and their associated muscles at pupation (Weeks and Truman, 1985; Weeks, 1987, 1999). Studies of changes in the pattern of gene expression in dying ISMs pioneered investigations of the molecular mechanisms of PCD in insects (Schwartz *et al.*, 1990a).

Descriptive studies of the death of neurons and muscles after adult eclosion in *D. melanogaster* (Kimura and Truman, 1990) foreshadowed the initiation in the 1990s of an intensive genetic analysis of PCD in fruit flies (reviews: McCall and Steller, 1997; Wing and Nambu, 1998a; Abrams, 1999; Bangs and White, 2000; Vernooy *et al.*, 2000). Efforts have focused primarily on the elucidation of the intracellular machinery of cellular suicide and on extracellular signals that trigger death in specific target cells. Two important current trends are the use of genomic approaches to identify genes associated with different forms of PCD, and the

development of *Drosophila* models of human neurodegenerative disease (Mutsuddi and Nambu, 1998; Gorski and Marra, 2002; Muqit and Feany, 2002; Driscoll and Gerstbrein, 2003; Lee *et al*., 2003). The underpinning of this work is the growing consensus within the field of cell death studies that mechanisms of cell death are broadly conserved across phylogeny (Yuan *et al*., 1993; Steller, 1995; Jacobson *et al*., 1997; Tittel and Steller, 2000; Vernooy *et al*., 2000) (see Section 2.5.5.4.1). Studies of muscle and nerve cell death in insects are, therefore, well positioned to address specific questions concerning metamorphosis, basic questions in cell biology, and topics of direct relevance to human health.

2.5.3.1. Earlier Reviews of PCD Relevant to Insects

The following previously published reviews provide essential background on PCD of insect nerve and muscle cells during metamorphosis: Truman *et al.* (1990, 1992), Schwartz (1992), and Weeks (1999). PCD in other insect tissues during development is reviewed in other chapters in this volume (see **Chapters 2.9** and **2.10**). Reviews covering the discovery of the first genes associated with PCD in *D. melanogaster* are found in McCall and Steller (1997), Wing and Nambu (1998a), Abrams (1999), Bangs and White (2000), and Vernooy *et al.* (2000). Autophagic and apoptotic cell deaths during *Drosophila* metamorphosis are compared in Thummel (2001); and a recent review of *Drosophila* as a model system for the study of PCD is found in Richardson and Kumar (2002). Overviews of PCD during animal development in general are provided in Milligan and Schwartz (1997), Jacobson *et al.* (1997), Meier *et al*. (2000), and Baehrecke (2002).

2.5.4. The *Manduca* Model

2.5.4.1. Choice of *Manduca sexta* as a Model System for the Study of PCD of Nerve and Muscle Cells

Insect endocrinologists and neurobiologists have long favored *M. sexta* (Lepidoptera: Sphingidae) because of its large size and ease of rearing in culture on artificial diet (Bell and Joachim, 1976; Arnett, 1993; Fahrbach, 1997). This species has a facultative rather than an obligatory diapause and, therefore, all life stages can be produced in the laboratory at any time of year. Development from egg to adult requires roughly 40 days. There are five successive larval stages (each referred to as an instar, so that the final larval stage is the fifth instar) and a single pupal stage. The adult lives approximately 10 days. The relatively large size of this insect in all life stages permits extensive surgical and endocrine manipulations. The central nervous system (CNS) consists of a dorsal brain and a ventral nerve cord. The abdominal portion of the ventral nerve cord retains its segmental organization of discrete thoracic and abdominal ganglia throughout the postembryonic period, a feature that facilitates anatomical, electrophysiological, and functional analyses.

The thoracic and abdominal musculature of *M. sexta* has also been fully described (Eaton, 1988). Importantly, many aspects of neuromuscular metamorphosis first described in *Manduca* have now also been identified in *Drosophila* (e.g., Kimura and Truman, 1990; Truman *et al*., 1994), despite evidence that the insect orders of Lepidoptera and Diptera have been evolving independently for at least 200 and, possibly, 300 million years (Hoy, 1994). This suggests that many aspects of neuromuscular metamorphosis, including PCD, are ancient in origin and highly conserved. This relationship permits phenomena first observed in *Manduca* to be subjected to indirect molecular genetic analysis by shifting to *Drosophila* for follow-up studies (e.g., Robinow *et al*., 1993). Conversely, orthologs of genes first identified in *Drosophila* can be cloned in *Manduca* and their developmental expression patterns determined (e.g., Nagy *et al*., 1991; Kraft and Jäckle, 1994).

The striking changes in the organization of the nervous and muscular systems that accompany lepidopteran metamorphosis result from a combination of postembryonic cell proliferation, modification of structures formed initially in the embryo, and PCD. While cell death is typically restricted to small populations of cells in the CNS, wholesale loss of entire bundles of muscle fibers in the periphery is more usual (Schwartz, 1992; Bayline *et al*., 1998). In fact, the coordinated loss of the ISMs following adult eclosion in *Manduca* offers a nearly ideal system for the study of PCD, because these cells are exceptionally large, easily accessible throughout the entire process of degeneration, and uncontaminated by persisting muscle fibers (**Figure 1**).

The ISMs of *Manduca* are composed of giant, syncytial fibers approximately 5 mm long and 1 mm in diameter. These embryonically derived cells are used by the larva for locomotion and by the pupa for defensive and respiratory behaviors. The ISMs also perform the major abdominal movements required for the eclosion behavior of the adult moth. The ISMs begin to atrophy at 3 days prior to adult eclosion, which results in a loss of 40% of muscle mass, although the ability to contract is maintained during this early phase (Schwartz and

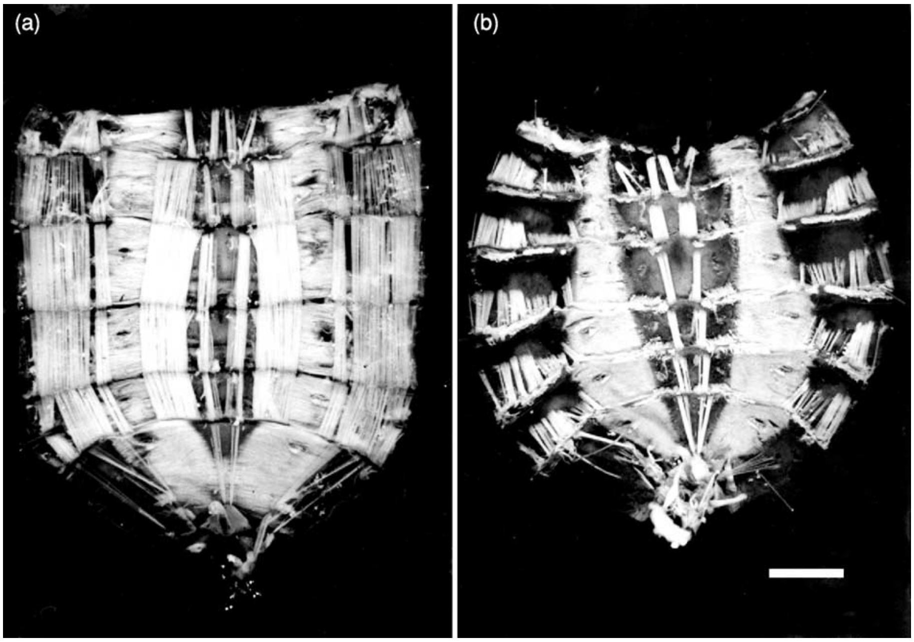

Figure 1 Loss of the intersegmental muscles (ISMs) following adult eclosion in *Manduca sexta*. These photographs display the abdominal musculature from animals (a) before and (b) 36 h after adult eclosion. The ISMs are the large vertical muscle fibers seen prior to eclosion. The small oblique muscles present after eclosion are external muscles that form during adult development and persist for the life span of the adult. Scale bar = 5 mm. (Adapted from Schwartz, L.M. **1992**. Insect muscle as a model for programmed cell death. *J. Neurobiol. 23*, 1312–1326.)

Ruff, 2002). Once the ISMs have participated in eclosion, they are no longer required for any adult behaviors and die during the subsequent 30 h (Schwartz, 1992). As described below (see Section 2.5.4.5), studies of the ISM death of *Manduca* have provided numerous insights into the cellular and molecular mechanisms of PCD.

2.5.4.2. Hormonal Regulation of Metamorphosis

As in all insects, metamorphosis in *Manduca* is regulated by two categories of developmental hormones, ecdysteroids and juvenoids (Truman and Riddiford, 2002; Nijhout, 1994) (see **Chapters 3.1**, **3.5**, and **3.7**). The ecdysteroids (see **Chapters 3.3** and **3.4**) are steroid hormones that exert their primary actions through members of the nuclear hormone receptor superfamily of proteins (Robinson-Rechavi *et al*., 2003) (see **Chapters 3.5** and **3.6**). The juvenile hormones are terpinoids (Nijhout, 1994) (see **Chapter 3.7**). At present, the cellular mode of action of juvenile hormones in metamorphosis remains to be defined and possibly involves more than one signaling pathway (Gilbert *et al*., 2000; Jones and Jones, 2000). Experiments on the hormonal regulation of neuromuscular metamorphosis in *Manduca* have clearly established that the changes in cell populations and connectivity that occur during neuromuscular metamorphosis are controlled by the direct actions of ecdysteroids and juvenile hormones on neurons, glia, and muscle (Bennett and Truman, 1985; Streichert *et al*., 1997) (see **Chapter 2.4**). Receptors for ecdysteroids have been localized to neuronal, glial, and muscle cell nuclei in *Manduca* (Bidmon and Koolman, 1989; Fahrbach and Truman, 1989; Bidmon and Sliter, 1990; Bidmon *et al*., 1992; Hegstrom *et al*., 1998; Fahrbach, 1992) (see **Chapter 2.4**).

2.5.4.3. PCD of Neurons during Metamorphosis

2.5.4.3.1. Background and overview Neuronal death during metamorphosis in *Manduca* involves motoneurons, interneurons, and identified peptidergic neurons. Most studies have focused on the death of motoneurons not only because of the greater ease of identification of specific neurons across individuals, but also because the highly visible degeneration of muscles during postembryonic development often suggests that innervating motoneurons will be lost, so that investigators in effect "know where to look." The presence of sexually dimorphic structures in the adult (see **Chapter 1.1**), such as the oviduct, also often suggests where PCD will be found in the CNS (Giebultowicz and Truman, 1984; Thorn and Truman, 1989). Dying peptidergic neurons can be identified after the detection of stage-specific patterns of antibody staining (Ewer *et al*., 1998). Cell counts and the presence of small pycnotic (shrunken) profiles often provide the only

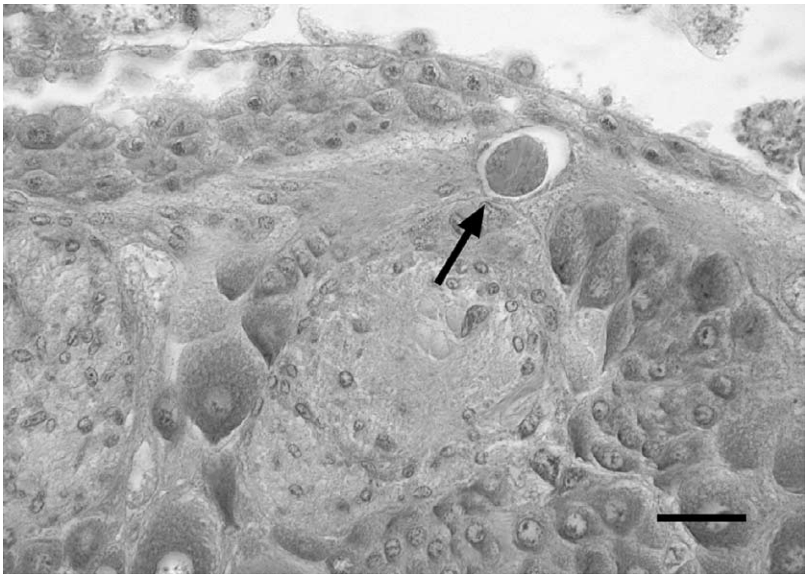

Figure 2 Transverse section (8 μm) through the first thoracic (prothoracic or T1) ganglion of the ventral nerve cord of *Manduca sexta* fixed in alcoholic Bouins 72 h after pupal ecdysis. After fixation, the ganglion was dehydrated, embedded in a paraffin-based medium, sectioned, and stained with hematoxylin and eosin. The arrow points to the shrunken, condensed profile of a motoneuron that has undergone programmed cell death (PCD). Because of the absence of phagocytosis in the ventral nerve cord during metamorphosis, the persisting fragments of such neurons are easily detected in insect nervous tissue prepared using routine histological techniques. Scale bar = 30 μm.

anatomical clues that interneurons have died, although the impact of such deaths on the function of neural circuits must be profound (Truman, 1983). The observation that the corpses of many dying neurons are not phagocytosed and therefore persist in the ganglia facilitates the identification and analysis of uniquely identified cells or populations well after the initiation of the PCD program.

Patterns of neuronal death during metamorphosis in *Manduca* have been mostly fully described for the motoneurons of the abdominal ganglia, although histological surveys of thoracic ganglia reveal that the PCD of neurons is also found in this tissue at the metamorphic transitions (S.E. Fahrbach, unpublished data) (**Figure 2**). At the larval–pupal transition, the best-studied examples of neuronal death are the proleg motoneurons (Weeks and Truman, 1985; Weeks, 1999). Studies of neuronal death associated with adult eclosion have focused primarily on the death of motoneurons (including the death of proleg motoneurons that persist after pupation) in the unfused abdominal ganglia, A3 through A5. In addition to the deaths of fully differentiated motoneurons and peptidergic interneurons, deaths of undifferentiated neurons occur in the imaginal nests of the segmental ganglia, both as the larvae feed and at the onset of metamorphosis (Giebultowicz and Truman, 1984; Booker and Truman, 1987a; Thorn and Truman, 1989; Booker *et al*., 1996). The PCD of neuroblasts that are active during postembryonic life terminates proliferation in specific lineages in both the segmental ganglia and the brain: in *Manduca*, the death of neuroblasts has been most comprehensively studied in the segmental ganglia (Booker and Truman, 1987a; Booker *et al*., 1996).

The emphasis on PCD of neurons at the larval–pupal and pupal–adult transitions in *Manduca* should not obscure the fact that the majority of larval neurons survive metamorphosis and become integral components of the adult nervous system, where they interact with other neurons derived from embryonic and postembryonic neurogenesis.

2.5.4.3.2. PCD of abdominal motoneurons during metamorphosis in *M. sexta* With rare exceptions (see Section 2.5.3.1), the abdominal motoneurons of *Manduca* are born during embryonic life. At both the larval–pupal and the pupal–adult metamorphic transitions, some of the larval motoneurons lose their muscle targets as a consequence of changes in the organization of the skeletal musculature (Levine and Truman, 1985). At the larval–pupal transition, some of these now targetless motoneurons die. Examples of motoneurons that undergo PCD at this time include some of the motoneurons that innervate muscles associated with the five pairs of abdominal prolegs, the locomotory appendages of the caterpillar that disappear at pupation (Weeks and Truman, 1985). In some segments however, the proleg motoneurons survive this round of PCD,

and after a period of dendritic regression, acquire new muscle targets in the developing adult (Weeks and Ernst-Utzschneider, 1989; Weeks *et al*., 1992). Targetless motoneurons, can therefore, either undergo PCD or become respecified. Experimental evidence suggests that the death of these motoneurons is triggered by endocrine cues independent of contact with target muscles (Bennett and Truman, 1985; Weeks and Truman, 1985). Abdominal motoneurons that lose their muscle targets after adult eclosion all die within 48 h of emergence, as the short (approximately 10 day) life of the adult apparently does not provide sufficient opportunity for respecification. It should be noted that unpublished observations from studies on the giant silkmoth *Antheraea pernyi* (J.W. Truman) and *Hyalophora cecropia* (S.E. Fahrbach) suggest that, in these species, motoneurons persist well after the death of the ISMs and, therefore, neither respecify nor die. This suggests that these motoneurons do not play out a hormonally triggered program of PCD and that, in contrast to many vertebrate motoneurons, their survival is not dependent on target-derived trophic signals. Comparative studies on a broader range of insect taxa are needed to complete our understanding of neuronal PCD following adult eclosion.

2.5.4.3.3. Sex-specific PCD of abdominal motoneurons during metamorphosis The populations of abdominal motoneurons are the same in male and female larvae, but during metamorphosis the genital segments undergo sex-specific morphological changes that are accompanied by a wave of sex-specific PCD in the ganglia that innervate these segments (Giebultowicz and Truman, 1984; Thorn and Truman, 1989). This is an example of equal opportunity sexual differentiation, as some motoneurons persist in males but degenerate in females, while others show the opposite pattern (Thorn and Truman, 1989). There is also a difference in the timing of sex-specific PCD relative to pupation, with most neurons in females dying during the first 2 days following pupation, while most neurons in males die during the third to the sixth day after pupation (Thorn and Truman, 1994a).

A particularly interesting example of sex-specific neuronal death in *Manduca* is seen in the case of some of the imaginal midline neurons (IMNs), which are highly unusual motoneurons, because they are born postembryonically during the fourth (penultimate) larval instar (Thorn and Truman, 1994a). These motoneurons innervate visceral rather than skeletal musculature, and some of them can be tracked during the larval–pupal transition, because they are immunoreactive with an antibody directed against molluscan small cardioactive peptide b (Thorn and Truman, 1994b). IMNs that innervate the sperm duct in males are absent from the terminal ganglia of females, while IMNs that innervate the oviduct in females are absent from the terminal ganglia of males. There is some evidence that contact with an appropriate target enhances the survival of the IMNs that innervate the sperm duct in males, another quite atypical aspect of their physiology (Thorn and Truman, 1994b).

2.5.4.3.4. PCD of identified peptidergic neurons during metamorphosis Two identified interneurons (INs) that contain crustacean cardioactive peptide (CCAP), cell 27 and IN 704, have been shown to undergo PCD within 36 h of adult eclosion (Ewer *et al*., 1998). Both cell 27 and IN 704 display increases in cGMP immunoreactivity during larval ecdyses, and cell 27 also shows this response at pupal ecdysis and at adult eclosion (Ewer *et al*., 1994; Ewer and Truman, 1997). Because application of CCAP to the isolated CNS can trigger the motor patterns of ecdysis, this set of neurons appears to be central to the control of molting behavior (Gammie and Truman, 1997; Mesce and Fahrbach, 2002). The death of peptidergic neurons involved in the control of ecdysis behavior, after the moth's molting career is finished, supports the hypothesis that obsolescent neurons are actively eliminated from the *Manduca* nervous system.

2.5.4.3.5. PCD in the brain during metamorphosis Detailed studies of specific regions of the *Manduca* brain have clearly demonstrated that newly generated neurons die during adult development. PCD is a prominent feature of the development of both the medulla and lamina cortices in the optic lobes (Monsma and Booker, 1996a). Both developmental hormones and retinal afferents appear to regulate this process (Monsma and Booker, 1996b). The extent of PCD in other regions of the developing *Manduca* brain is largely unstudied. A general role for ingrowing sensory afferents in the regulation of neuronal survival is suggested by the sex differences that arise in populations of antennal lobe interneurons, as a result of sexual dimorphisms in the antennae (Schneiderman *et al*., 1982).

2.5.4.3.6. PCD of imaginal nest cells during metamorphosis Postembryonic neurogenesis is a major source of adult populations of neurons in holometabolous insects, yet a curious aspect of this phenomenon is that many neurons born during the postembryonic period die before they can differentiate. New neurons, which accumulate in nests

around their parent neuroblast, die in a nest- and segment-specific pattern during the feeding larval stages and the onset of metamorphosis (Booker *et al.*, 1996). Studies using bromodeoxyuridine as a marker for mitosis have produced estimates that between a third and 70% of imaginal neurons die within 24 h of their birth (Booker *et al.*, 1996). There is some evidence that the death of imaginal neurons and their associated neuroblasts in *Manduca* is regulated by developmental hormones (Booker and Truman, 1987b).

2.5.4.4. Regulation of PCD in the Nervous System during Metamorphosis

Neuronal death during insect metamorphosis has been described as hormone dependent, segment specific, and target independent (Truman *et al.*, 1992). Considerable experimental evidence supports each of these claims, although, in some special cases, a role for cell–cell interactions is implicit in the data.

The ecdysteroids are important regulators of PCD in the nervous system, acting to couple neuronal death with other metamorphic changes. It is important to note that the ecdysteroid cue for triggering metamorphic neuronal death can be either a rising or a falling titer, depending upon developmental stage. For example, the decline in circulating levels of 20E that occurs at the end of adult development prior to adult eclosion is the cue for the death of abdominal motoneurons at this time, and treatment with exogenous ecdysteroid at this time blocks the initiation of PCD (Truman and Schwartz, 1984). By contrast, it is the prepupal rise in circulating ecdysteroids that is responsible for the larval–pupal transition death of the motoneurons in abdominal ganglia A5 and A6, which innervate the accessory plant retractor muscle of the prolegs (Weeks and Ernst-Utzschneider, 1989; Weeks *et al.*, 1992; Zee and Weeks, 2001). The response of these proleg motoneurons to the steroid signal, however, is segment specific. Homologous neurons in abdominal ganglia A3 and A4 persist through the pupal stage and adult development, but then undergo PCD within 24 h of adult eclosion (Zee and Weeks, 2001). These responses to 20E, as well as the segment specificity of the response at different stages in development, are retained when individual proleg motoneurons are cultured *in vitro*, providing strong evidence for the cell-autonomous, target-independent nature of these PCDs (Streichert *et al.*, 1997; Hoffman and Weeks, 1998).

It is to be assumed that ecdysteroids exert their control on the timing of PCD by means of transcriptional regulation, but the target genes for steroid hormone action have not been identified in *Manduca*. In addition, the tissues of *Manduca* and other insects express several different isoforms of the ecdysone receptor, which may have varying relationships to cell fate. In *Drosophila*, the expression of the A isoform of the ecdysone receptor (EcR-A) has been directly correlated with the occurrence of post-eclosion neuronal death in the CNS (Robinow *et al.*, 1993). Whether or not a similar relationship prevails in *Manduca* neurons remains to be determined, although autoradiographic evidence has demonstrated that *Manduca* motoneurons fated to die at the start of adult life display nuclear concentration of radiolabeled ecdysteroids (Fahrbach and Truman, 1989).

Evidence that other signals may fine-tune the timing of the death of neurons during metamorphosis comes from several sources. Adult *M. sexta* emerge from their pupal cuticle in an underground pupation chamber, and must then dig to the surface before inflating their wings. Adult moths forced to continue digging hours beyond the time this behavior would normally cease, exhibited delayed death of abdominal motoneurons (Truman, 1983). In addition, transection of the ventral nerve cord, prior to adult eclosion, blocks the death of specific motoneurons after adult eclosion in ganglia posterior to the point of transection, even in moths in which the levels of 20E undergo their normal decline (Fahrbach and Truman, 1987).

A well-studied example of a spared abdominal motoneuron is MN-12 (**Figure 3**). Subsequent to ventral nerve cord transection, this supernumerary member of the adult abdominal ganglion maintains both its normal central arborizations and electrophysiological properties, implying that the cell death program has been completely blocked in the absence of a descending signal (Fahrbach *et al.*, 1995; DeLorme and Mesce, 1999). Treatment of cultured abdominal ganglia with extracts prepared from ventral nerve cord restores the normal pattern of cell death to MN-12, but the active factor in the extracts remains to be identified (Choi and Fahrbach, 1995). Other examples of motoneuron death, such as the death of the accessory planta refractors (APRs) at the larval–pupal transition, however, are unaffected by cutting of the connectives prior to the normal time of death (Weeks and Davidson, 1994). This suggests that the phenomenon of interganglionic cell death signaling affects only a limited set of cells.

Because of the scattered, episodic nature of neuronal death during metamorphosis, and the unavailability of transgenic *Manduca* for analysis, relatively little is known about the molecular mechanisms of neuronal death in this species. Hormone-dependent neuronal death is blocked by treatment with inhibitors of transcription or translation,

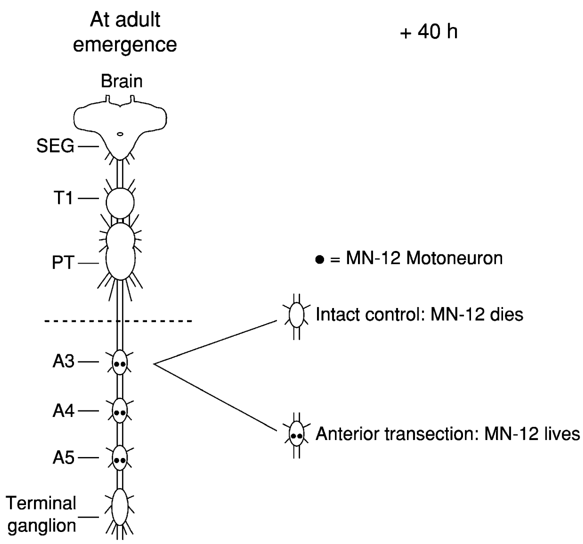

Figure 3 Schematic diagram of the central nervous system of an adult *Manduca sexta* moth. The MN-12 motoneurons in the abdominal ganglia normally undergo programmed cell death (PCD) by 40 h after adult emergence (eclosion), but are spared this fate if connections to the anterior nervous system are severed just posterior to the pterothoracic ganglion (Fahrbach and Truman, 1987). The dashed line indicates the point of anterior nerve cord transection. A3, A4, and A5, abdominal ganglia; PT, pterothoracic ganglion; SEG, subesophageal ganglion; T1, prothoracic ganglion.

suggesting the existence of an active gene-mediated cell death program (Weeks *et al.*, 1993; Fahrbach *et al.*, 1994; Ewer *et al.*, 1998; Hoffman and Weeks, 1998). In support of the hypothesis that PCD of *Manduca* neurons requires protein synthesis, a two-dimensional polyacrylamide gel electrophoresis analysis of protein patterns in the *Manduca* ventral nerve cord revealed changes associated with programmed neuronal death at adult eclosion (Montemayor *et al.*, 1990). Mitochondrial involvement in the death of APRs has been shown by studies in which inhibition of caspase activity blocked the death of cultured proleg motoneurons (Hoffman and Weeks, 2001). Ultrastructural studies of dying *Manduca* neurons are uncommon, but studies of the motoneurons that innervate the ISMs and of APR motoneurons indicate that neuron death in *Manduca* during metamorphosis is autophagic rather than apoptotic (Stocker *et al.*, 1978; Kinch *et al.*, 2003).

Immunostaining studies, in which the distribution of several death-associated gene products (initially identified from a screen of dying moth muscle; see Section 2.5.5.4.3) was examined in the segmental ganglia, failed to provide a reliable correlation of enhanced ubiquitin- or multicatalytic proteinase-immunoreactivity within dying neurons (Fahrbach and Schwartz, 1994; Hashimoto *et al.*, 1996), despite an association of these gene products with PCD in insect skeletal muscles (Jones *et al.*, 1995; Haas *et al.*, 1995). This discrepancy in gene expression during PCD in neurons and muscles remains unexplained. By contrast, one gene product, expressed by both dying neurons and degenerating muscles in *Manduca*, is apolipophorin III, a finding that suggests that this molecule has functions in addition to its role in lipid transport (Sun *et al.*, 1995).

2.5.4.5. PCD of Muscles during Metamorphosis

The ISMs of *Manduca* (**Figure 1**) are the major abdominal muscles of the larva, pupa, and pharate adult. The ISMs are divided into three separate pairs of bilaterally symmetric bundles, each of which attaches to the cuticle at the intersegmental boundaries. These muscles initially form in the embryo and span eight of the abdominal segments in the larva. The ISMs provide the major propulsive force for both hatching and subsequent larval locomotion. Following pupation, the muscles in the first two and last two abdominal segments die and rapidly disappear. The muscles in the middle four segments persist throughout metamorphosis and are used for the defensive and respiratory movements of the pupa. Following adult eclosion, these remaining ISMs undergo PCD and are lost during the subsequent 30 h. While the molecular basis for this segmental fate determination has not been examined, presumably it is established early in embryogenesis due to the actions of gap, pair-rule, and segment-polarity genes (Bejsovsec and Wieschaus, 1993; DiNardo *et al.*, 1994; French, 2001; Sanson, 2001).

The nuclear changes that accompany ISM death display none of the features of apoptosis (Schwartz *et al.*, 1993) (**Figure 4**). The chromatin does not become electron dense but remains dispersed throughout the nucleoplasm. In addition, agarose gel electrophoresis of ISM genomic DNA fails to reveal apoptotic ladders, although activation of DNases may occur as a very late event, after membrane integrity has been lost. Ultrastructurally, there is an increase in autophagic vesicles, and these cells are throught to die by autophagy (Lockshin and Beaulaton, 1974, 1979).

Following PCD in most organisms, the cell corpse is phagocytosed by neighboring cells or circulating macrophage-like cells (see Section 2.5.2.1). A classic example of this phenomenon is found in amphibian metamorphosis, where the massive tail musculature is lost during the short transition from larva to adult (Weber, 1964; Watanabe and Sassaki, 1974). During this process, the muscle fibers become

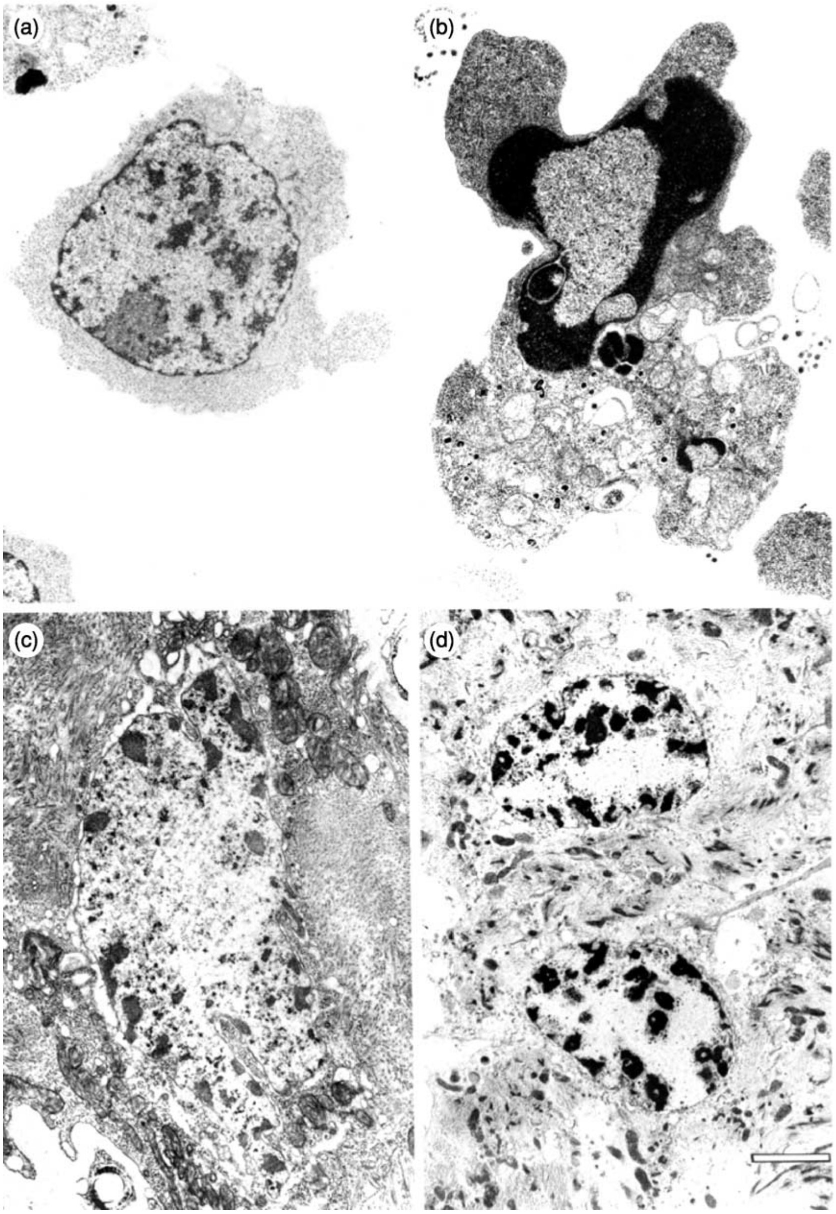

Figure 4 Transmission electron micrographs comparing the morphology of mouse lymphocyte apoptosis (a and b) with the autophagic death of the ISMs of *Manduca* (c and d). The mouse T cell hybrid cell line D011.10 was induced to die with the glucocorticoid dexamethasone, and examined either at time zero (a) or 16 h after exposure (b). These cells die by apoptosis and display many of the classical features of the program, including membrane blebbing and the deposition of electron-dense chromatin along the inner surface of the nuclear envelope. These images contrast those of normal *Manduca* ISMs (in a day 16 pupa; c) and dying ISMs (at 18 h posteclosion; d). During autophagy, the nuclei round up and the chromatin remains dispersed in the nucleoplasm.

decorated with macrophages that, in turn, contain identifiable remnants of skeletal muscle debris (Metchnikoff, 1892; Nishikawa *et al*., 1998).

While dying muscles in insects are often phagocytosed by hemocytes (Crossley, 1968), this is not universally the case (Jones *et al*., 1978). In particular, the death of the ISMs, following adult eclosion in moths, does not attract macrophage-like cells or rely on phagocytosis for resolution (Beaulaton and Lockshin, 1977). Although this cannot be accounted for solely by trivial reasons, such as an absence of circulating macrophages capable of phagocytosing foreign bodies (Jones and Schwartz, 2001), estimates of ISM volumes and hemocyte numbers in adult *Manduca* suggest that animals would require at least an order of magnitude greater number of phagocytic cells than has been shown to reside in the hemolymph (Jones and Schwartz,

2001). While the ISMs of adult animals are not phagocytosed, some of the ISMs that die following pupation in *Manduca* appear to behave differently. Rheuben examined the death of mesothoracic muscles in pupae, and observed an intimate association between phagocytic hemocytes and the sarcolemma (Rheuben, 1992). The phagocytes were well spaced along the fibers and appeared to specifically degrade the basal lamina. One difference between the ISMs and the mesothoracic fibers is that the latter are not completely degraded during development. Instead, they act as scaffolds for myoblasts that remodel the fibers during the formation of adult muscle fibers. Phagocytes may play a more significant role in facilitating tissue remodeling, as opposed to cell death.

2.5.4.5.1. Endocrine control of ISM death The timing of ISM death must be precisely coordinated with other metamorphic events or the animal might suffer disastrous consequences. For example, premature loss of the ISMs in moths would leave the animal trapped within the pupal cuticle and locked in either a cocoon or an underground chamber. Delays in ISM death might also have deleterious consequences, possibly depriving the adult of essential nutrients required for gametogenesis.

As described above (see Section 2.5.4.4), the titer of ecdysteroids serves as an endogenous developmental time reference, that can be used by the different organs of the pupa to coordinate developmental decisions. Sequential declines in the ecdysteroid titer serve to coordinate developmental changes in the tissues, including the timing of ISM death (Schwartz and Truman, 1983).

Early reports identified the cessation of motor neuron activity as the proximal trigger for ISM death (Lockshin and Williams, 1965b). This hypothesis was subsequently proven incorrect, when it was found that normal timing of ISM death in *A. polyphemus* was not altered either by silencing motoneuron activity with the highly specific sodium channel blocker tetrodotoxin or by the removal of the entire ventral nerve cord (Schwartz and Truman, 1983, 1984b). Instead, it was shown that the peptide eclosion hormone (EH) acts to trigger ISM death in this species (Schwartz and Truman, 1984b; 1984a). The EH acts via cGMP, and the description of its role in ISM death represented the first study demonstrating that cGMP met all of Earl Sutherland's requirements for identifying a second messenger for a hormone action (Sutherland, 1972; Schwartz and Truman, 1984a). The capacity of EH to act on the ISMs is itself under the control of circulating ecdysteroids, as a decline in circulating 20E is required to determine both the timing of EH release and the developmental capacity of the muscles to respond to this trigger (Truman, 1984; Schwartz and Truman, 1984b).

2.5.4.5.2. Physiology of ISM death The size of the ISMs and the coordinated nature of the developmental changes that take place in this tissue during metamorphosis facilitate the examination of the physiological changes that accompany naturally occurring muscle atrophy and death. Under laboratory conditions, metamorphosis in *Manduca* takes 18 days, with adult eclosion taking place late on day 18. On day 15 of adult development, the mass of the ISMs begins to decline and, during the subsequent 3 days, ISMs lose 40% of their mass. This preeclosion program of atrophy is nonpathological, and the muscles retain virtually all of their normal physiological responses, including force/cross-sectional area and sensitivity to calcium ions in skinned fiber preparations. This suggests that the reduction in muscle mass, observed during the atrophy phase, reflects a generalized enhancement of protein turnover rather than a selective destruction of specific contractile proteins. Ultrastructural studies by Lockshin and Beaulaton (1979) have shown that entire contractile bundles are lost during this phase.

In *Manduca*, the ISMs begin the death program coincident with adult eclosion, late on day 18 after pupation, with the muscles beginning to lose mass at a rate of approximately $4\%\,h^{-1}$ (Schwartz and Truman, 1982). Concurrently, there is a slow, progressive depolarization of the fibers at a rate of $\sim 2.5\,mV\,h^{-1}$ (Runion and Pipa, 1970; Schwartz and Ruff, 2002). By 24 h posteclosion, reliable resting potentials can no longer be recorded. The retention of a resting potential during the active phase of ISM death verifies that the cells are not undergoing a necrotic process. While there is little change in the organization of the contractile apparatus during the atrophy phase, the postemergence period is marked by profound sarcomere disruption (Lockshin and Beaulaton, 1979). Whole filaments disappear rapidly, with a preferential loss of thick filaments relative to thin filaments (Beaulaton and Lockshin, 1977). During this same period, mitochondria are lost, autophagic vacuoles form, and the T tubule system swells.

Not surprisingly, there are physiological consequences that accompany these dramatic changes in ISM structure. The fibers rapidly weaken, even when force is normalized to cross-sectional area. This is true for twitches, and for tetanus and caffeine-induced contractions (Schwartz and Ruff, 2002). There are also defects in the ability of the

contractile apparatus to respond to free calcium in either intact muscles or skinned fiber preparations.

2.5.4.5.3. Patterns of gene expression during PCD of ISMs While ISM atrophy appears to involve an increase in protein catabolism over synthesis (Haas *et al.*, 1995), there is incontrovertible evidence that the posteclosion death of these cells involves the implementation of a new developmental program. Insights into the molecular mechanisms of ISM death were provided in 1969, when Lockshin reported that the death of silkmoth ISMs is blocked by inhibitors of RNA or protein synthesis (Lockshin, 1969). These results are similar to those reported for PCD in other insect tissues, including the nervous system (see Section 2.5.4.4), as well as other taxa such as amphibians (Weber, 1965). Taken together, these data provided some of the earliest evidence that the ability of cells to die required *de novo* gene expression.

To confirm and extend this hypothesis, Schwartz and colleagues made cDNA libraries from condemned, day 18 ISM RNA, and screened them for differentially expressed genes. While the vast majority of ISM genes were found to be constitutively expressed, a small number were observed to be either repressed or induced when the muscles became committed to die. The cloning of these new sequences from day 18 ISMs represented the first published report of death-associated gene expression changes from any organism (Schwartz *et al.*, 1990a). Subsequent characterization of these sequences has provided new information about the molecular mechanisms of PCD.

Among the genes that are repressed, when the ISMs become committed to die, are actin and myosin heavy chain (Schwartz *et al.*, 1993) (**Figure 5**). These transcripts are among the most abundant in the muscle throughout metamorphosis, but they begin to disappear late on the day before adult eclosion (day 17), coincident with the commitment to die. By the time of adult eclosion, they are almost undetectable on Northern blots. A single injection of 25 μg of 20E on day 17 is sufficient to delay both the ISM death on day 18 and the loss of these transcripts, thus linking this change in gene expression to the commitment of the muscles to die.

Given that most muscle genes are constitutively expressed during ISM atrophy and death, there must be some advantage to reducing selectively the

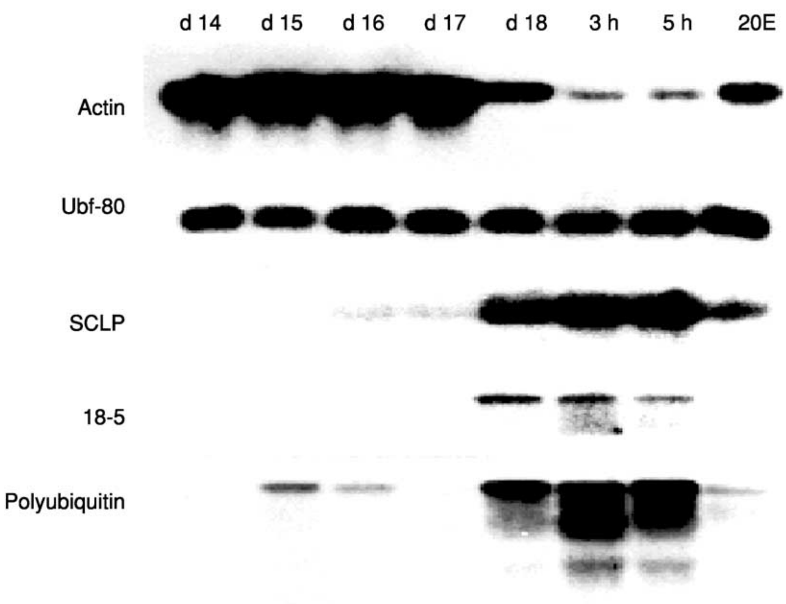

Figure 5 Changes in the patterns of gene expression during the atrophy and death of the intersegmental muscles in *Manduca*. RNA was isolated from the ISMs at the time indicated and fractionated by size in agarose. After transfer to a nylon membrane, the Northern blots were hybridized with different cDNAs isolated from *Manduca*. The expression of some genes, like actin and myosin heavy chain (not shown), is repressed when the ISMs become committed to die on day 18. When animals are injected with 20-hydroxyecdysone (20E) on day 17 of pupal–adult development and examined 5 h after the normal time of eclosion, the loss of these transcripts is reduced. The majority of ISM genes are constitutively expressed throughout the period of ISM development examined, as shown here for the *ubiquitin fusion*-80 (*Ubf-80*) gene. A final class of genes is induced when the ISMs become committed to die, including: *SCLP* (small cytoplasmic leucine-rich repeat protein), *polyubiquitin*, and the as yet uncharacterized *18-5* gene. Pretreatment with 20E delays the accumulation of these induced transcripts. d, day of pupal–adult development; h, hours – postadult eclosion.

abundance of actin and myosin heavy chain mRNA. One possible explanation is that it allows the muscles to change, in a dramatic fashion, their developmental program from one of homeostasis to another of death, by allowing newly expressed transcripts to accumulate and effectively compete for the cellular translational machinery.

One mechanism for reducing transcript abundance is transcriptional repression. A complementary mechanism is to enhance transcript degradation. In fact, it was found that there is a transient increase in endogenous ISM RNAse activity on day 17, which facilitates the removal of all transcripts prior to the induction of new gene expression (Cascone and Schwartz, 2001). This coordinated control of transcription and degradation may allow the muscles to shift developmental programs extremely rapidly. It has yet to be determined whether a similar strategy is used by other organisms during development.

In addition to transcript loss, several newly expressed death-associated cDNAs have been cloned and characterized from the ISMs (Schwartz *et al*., 1990a). While the majority of these cDNAs encoded previously uncharacterized genes, the first one to be sequenced was shown to be the product of the polyubiquitin gene (Schwartz *et al*., 1990b). Ubiquitin is a 76 amino acid peptide that is the most highly conserved protein across phylogeny. At the protein level, insect and human ubiquitins are identical (review: Rechsteiner, 1988). The posttranslational covalent attachment of ubiquitin to selected lysine residues on substrate proteins serves as a molecular tag, to help target proteins to specific fates within the cell (Murphey and Godenschwege, 2002; Schwartz and Hochstrasser, 2003). The addition of single ubiquitin moieties serves to target proteins to specific subcellular locations, while the addition of multiple head-to-tail ubiquitin chains promotes binding to the 26S proteasome. This multisubunit protease then releases the ubiquitin, unfolds the substrate and rapidly degrades it to small peptides.

In *Manduca* ISMs, expression of polyubiquitin mRNA increases transiently on days 15 and 16 of adult development, and then accumulates to prodigious levels on day 18, the day of adult eclosion. The early expression of ubiquitin is associated with the increased turnover of contractile proteins that accompanies the atrophy program that begins on day 15 and a transient increase in ubiquitin-dependent proteolysis (Haas *et al*., 1995). On day 18, there is a coordinated exponential increase in the expression of the entire ubiquitin-proteasome pathway, including ubiquitin conjugation, ubiquitin-dependent proteolysis, and proteasome subunit expression. In fact, it has been found that there is a coordinated exponential increase in the expression of both 20S and 26S proteasome subunit proteins, at both the mRNA and protein levels (Schwartz *et al*., 1990b; Dawson *et al*., 1995; Haas *et al*., 1995; Jones *et al*., 1995; Takayanagi *et al*., 1996; Low *et al*., 1997). Placed in a broader context, this enhancement in ubiquitin-dependent proteolysis is presumably adaptive, because the ISMs are not phagocytosed and, therefore, the liberation of cellular constituents requires a cell-autonomous mechanism.

Other previously described transcripts were also identified in the condemned ISMs, but their relationship to PCD remains unknown. For example, the abundance of apolipoprotein III (apoLp-III) is dramatically induced, at both the RNA and protein levels, in both the ISMs and in certain dying interneurons (Sun *et al*., 1995). ApoLp-III is synthesized predominantly in the fat body and normally associates with lipophorin in the hemolymph to facilitate lipid transport. The role of apolipoprotein in PCD is mysterious, particularly since the ISMs do not express lipophorin.

The majority of cDNAs isolated in the ISM screen encoded novel proteins of unknown function. For example, one of these cDNAs encodes a small protein that is composed of multiple leucine-rich repeat protein–protein interaction motifs (Kuelzer *et al*., 1999). Termed *SCLP* (small cytoplasmic leucine-rich repeat protein), this gene is dramatically induced at both the RNA and protein levels. Exploiting a paradigm for the study of genes initially isolated in moths, transgenic flies were generated that express *Manduca SCLP* under the control of the Gal4 protein upstream activating sequence (UAS) using the *P* element system that allows gene expression to be targeted to specific tissues in the fly. Ectopic expression of *SCLP* in a variety of tissues failed to reveal an overt phenotype, suggesting that overexpression of *SCLP* is nonpathological (Kuelzer *et al*., 1999). Studies employing loss-of-function mutations will be needed to define the role of *SCLP* in development and death.

In contrast to *SCLP*, other novel death-associated transcripts from *Manduca* ISMs have been shown to play key roles in PCD. The characterization of two such genes has provided insights into the development and death of muscle in mammals as well as insects. The first of these genes is *DALP* (death-associated LIM-only protein). In contrast to the genes described above, *DALP* is induced on day 17, well in advance of the other death-associated cDNAs from *Manduca* ISMs (Hu *et al*., 1999). Expression of the DALP protein is restricted to the ISMs and is not detected in the flight muscle, fat body, Malpighian tubules, ovary/eggs or male

sexual accessory gland. The most significant structural feature of the DALP protein is the presence of one perfect and two imperfect LIM domains, structural motifs that consist of paired zinc fingers, which participate in protein–protein interactions (Leon and Roth, 2000; Laity *et al*., 2001). While many LIM proteins also possess a homeodomain, DALP belongs to the subfamily of LIM-only proteins (LMO) that lack this DNA binding motif.

As with SCLP, the function of *Manduca* DALP was explored using transgenic flies (Hu *et al*., 1999). Ectopic expression of *Manduca DALP* in the abdominal intersegmental muscles of fly pupae resulted in the disorganization of the contractile apparatus and subsequent muscle atrophy (**Figure 6**). Targeted mutations in the LIM domain blocked muscle atrophy, suggesting that the observed effects of ectopic *DALP* expression were dependent on expression of the intact functional protein.

Further insights into the function of DALP were gained by examining the effects of expressing *Manduca DALP* in the mouse myoblast C_2C_{12} cell line (Hu *et al*., 1999). This muscle satellite cell line has been extensively used as a model for examining skeletal muscle differentiation in mammals. C_2C_{12} cells can be maintained as a stable, nontransformed line that ceases cycling and differentiates into multinucleated myotubes following incubation in a low serum differentiation medium (Yaffe and Saxel, 1977). Expression of *DALP* was able to block the ability of C_2C_{12} cells to differentiate into myotubes by blocking the induction of MyoD, a basic helix–loop–helix muscle transcription factor required for differentiation. These effects of DALP were overcome by cotransfecting the cells with an expression vector driving ectopic MyoD. In addition to blocking differentiation, DALP greatly enhanced the probability of cell death. Identical data were obtained when C_2C_{12} cells were forced to express ectopic *Hic-5* (hydrogen peroxide-inducible clone-5), the mammalian ortholog of *DALP*. Taken together, these data demonstrate that DALP and Hic-5 are phylogenetically conserved proteins that function as negative regulators of muscle differentiation and survival in both insect and mammalian cells. These results also validate the view that general conclusions about PCD and differentiation may be drawn from the study of insect metamorphosis.

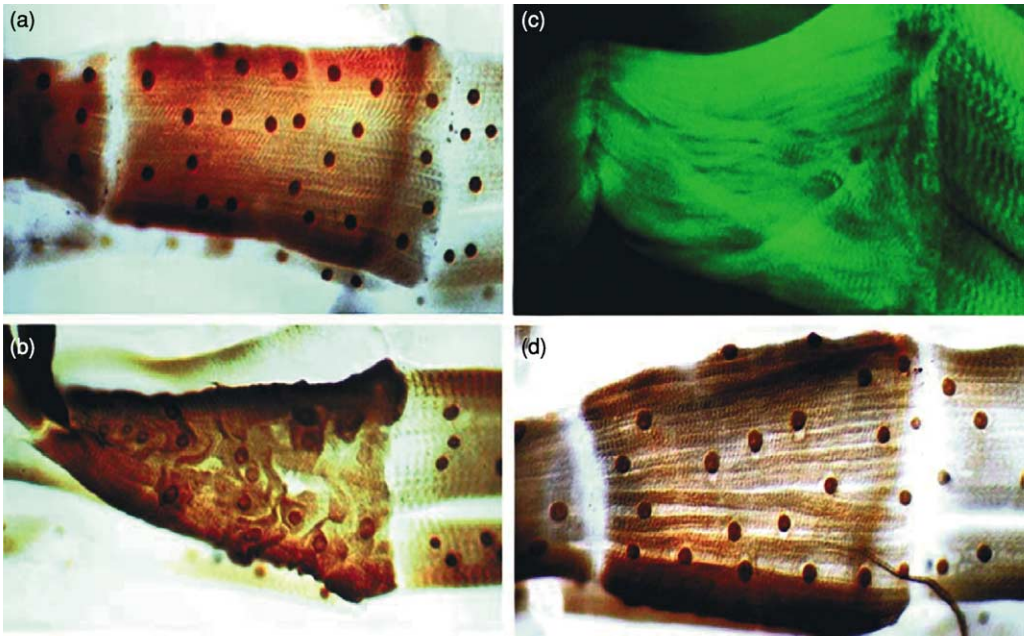

Figure 6 The effects of ectopic *DALP* expression in *Drosophila* skeletal muscle. (a) Bacterial β-galactosidase was expressed in *Drosophila* ISMs using the Gal4/UAS expression system. Expression (nuclear as well as cytoplasmic) was monitored via anti-β-galactosidase immunocytochemistry. (b) The same Gal-4 enhancer trap line was used to coexpress β-galactosidase and moth *DALP* in the ISMs. *DALP* expression was independently shown to parallel that of β-galactosidase, monitored in this panel by immunohistochemistry. (c) The organization of the contractile apparatus was visualized using fluorescein isothiocyanate (FITC)-labeled phalloidin in separate animals expressing ectopic *DALP*. In this panel, the disorganization of the contractile apparatus is evidenced by the loss of the sarcomeres that are obvious in the two fibers at right. (d) The WHPEHF motif was deleted from *DALP* and coexpressed with *β-galactosidase* in the ISMs. Muscles retained normal appearance and were contractile. Note that the triangular muscle in these assays is muscle 31 and is about 260 μm long. (Reproduced from Hu, Y., Cascone, P., Cheng, L., Sun, D., Nambu, J.R., Schwartz, L.M. **1999**. Lepidopteran DALP, and its mammalian ortholog Hic-5, function as negative regulators of muscle differentiation. *Proc. Natl Acad. Sci. USA 96*, 10218–10223.)

The last gene of the moth ISMs to be cloned and analyzed to date encodes a protein named Acheron (Ach; after the river that must be crossed to reach to the realm of the dead in Greek mythology). Acheron is undetectable in ISMs until early on day 18, when it begins to accumulate to high levels (Wang, Valavanis, Sun, and Schwartz, unpublished data). This increase in *Acheron* expression on day 18 can be blocked with a single intrathoracic injection of 25 μg of 20E on day 17. *Acheron* expression is not restricted to the ISMs, however, because Northern blot analysis revealed low levels of expression in the fat body and flight muscle but not in Malphigian tubules, ovaries, or the male sexual accessory gland. Because the ovary is composed predominantly of unfertilized oocytes, these data suggest that *Acheron* is not a maternal transcript.

Database analysis revealed a human expressed sequence tag (EST) that shares 59% identity and 68% similarity over 86 amino acids with *Manduca Acheron* (Wang, Valavanis, Sun, and Schwartz, unpublished data). Using this sequence as a probe, full-length human and mouse homologs of Acheron were cloned. It was found that they display about 31% identity and 40% similarity to *Manduca Acheron*.

Mammalian *Acheron* expression has also been studied in the mouse C_2C_{12} line (Wang, Valavanis, Sun, and Schwartz, unpublished data). It appears that *Acheron* acts near the apex of the genetic hierarchy that regulates myoblast survival and differentiation, because it is required for myotube formation and, when its activity is blocked with either antisense or a dominant-negative form of the protein, differentiation is blocked. Acheron was also found to block the expression of the anti-apoptotic protein Bcl-2 (B cell lymphoma 2), which, in turn, enhances the death of cells. These data suggest that Acheron, like DALP/Hic-5, acts to control key developmental decisions in muscle cells, including the initiation of PCD.

2.5.5. The *Drosophila* Model

2.5.5.1. Choice of *Drosophila melanogaster* as a Model System for the Study of PCD of Nerve and Muscle Cells

The successful application of genetics to define the molecular controls of PCD in the nematode *Caenorhabditis elegans* provided impetus to apply this approach to the study of PCD in the fruit fly, *D. melanogaster* (Diptera: Drosophilidae). Kimura and Truman (1990) extended earlier observations of muscle death during *Drosophila* metamorphosis by systematically documenting the accompanying post-eclosion neuronal death in the fused ventral ganglia. Injection of living flies with a toluidine blue solution revealed numerous examples of dying neurons in the dorsal and lateral regions of the abdominal and metathoracic neuromeres (Kimura and Truman, 1990). These investigators also mapped changes in both the head and abdominal musculature, before and after eclosion, by using polarized light microscopy to monitor the loss of birefringent muscle fibers. Several studies described below (see Section 2.5.5.3.1) have made profitable use of these baseline observations to explore ecdysteroid regulation and molecular mechanisms of PCD in the nervous system of adult flies (Robinow *et al*., 1993, 1997; Draizen *et al*., 1999).

However, the first identification of novel cell death genes in *Drosophila* was not based on the study of metamorphosis, but instead resulted from a screen for aberrant patterns of cell death in embryos carrying homozygous chromosomal deletions, carried out in the laboratory of Hermann Steller (White *et al*., 1994). Embryo staining with the vital dye acridine orange was used to compare wild-type embryos with 129 different deletion strains. Chromosomal deletions that remove a small region at 75C on chromosome 3L, such as Df(3L)H99, were found to exhibit a blockade of both developmental and X-irradiation induced apoptosis. Subsequent studies led to the identification of four related proapoptotic genes that reside within a 300 kb interval in this region, *reaper* (*rpr*), *head involution defective (hid)*, *grim*, and *sickle (skl)* (White *et al*., 1994; Grether *et al*., 1995; Chen *et al*., 1996; Christich *et al*., 2002; Srinivasula *et al*., 2002; Wing *et al*., 2002) (**Figure 7**). These linked genes are all transcribed in the same direction and are expressed predominantly in doomed and dying cells. As will be described below, proper regulation of cell survival in *Drosophila* involves precise transcriptional control of this gene complex.

Reaper, Grim, and Sickle are all small proteins (65, 138, and 108 amino acids respectively), while Hid is substantially larger at 410 amino acids. Each of these proteins possesses a related 14 amino acid region at the N-terminus, the RHG (Reaper, Hid, Grim) motif or IBM (inhibitor of apoptosis (IAP)-binding-motif) that has potent proapoptotic activities. The RHG and IBM motifs of Reaper and Grim are very similar: they share 71% identity, and three of the four amino acid differences are conservative substitutions. Surprisingly, despite this similarity, *in vivo* studies have shown that these domains possess distinct death-inducing activities (Wing *et al*., 1998b). Reaper, Grim, and Sickle also share a

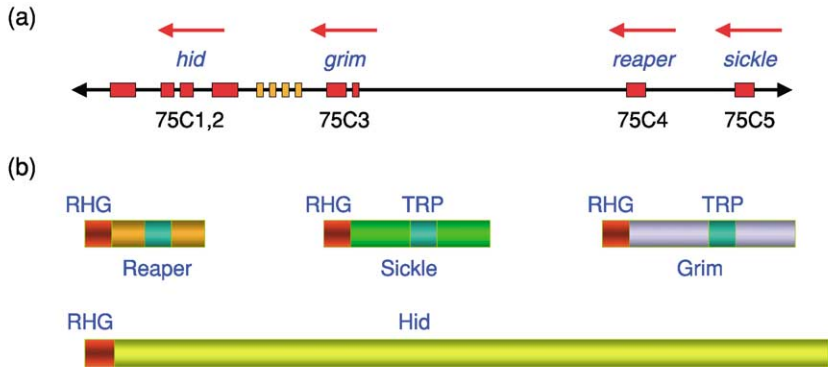

Figure 7 The *grim-reaper* genes encode related proapoptotic proteins. (a) The *hid, grim*, *reaper*, and *sickle* genes all reside within a 300 kb interval in the 75C region of chromosome 3L of *Drosophila melanogaster*. The four genes are transcribed in the same direction (arrows above genes) and are expressed predominantly in doomed and dying cells. No genes are predicted to reside between *grim* and *reaper*, or *reaper* and *sickle*, while four unrelated genes (orange blocks) reside between *hid* and *grim*. (b) *reaper*, *sickle*, and *grim* encode small proteins that contain a related N-terminal RHG motif/IBM as well as a C-terminal Trp block/GH3 domain. Hid is a substantially larger protein that also contains an RHG motif but does not exhibit strong sequence similarity to the Trp block/GH3 domain.

second region of sequence similarity, the 15 amino acid Trp block or Grim Helix 1, 2, and 3 (GH3) domain (**Figure 7**), which also has proapoptotic functions (Wing *et al*., 2001; Claveria *et al*., 2002). While Hid possesses four regions that resemble a Trp block/GH3 domain, the level of similarity is much lower. Together, the *reaper*, *hid*, *grim*, and *sickle* genes should be considered a genetic complex that controls apoptosis.

The considerable insights into the molecular mechanisms of PCD gained by further studies of this complex during *Drosophila* embryonic development and metamorphosis are described in detail below (see Section 2.5.5.4). In addition, it should be noted that targeted ectopic expression of these genes in cells that are normally fated to live, provides a valuable tool for producing cell-specific lesions of the CNS (McNabb *et al*., 1997; Renn *et al*., 1999; Rulifson *et al*., 2002; Park *et al*., 2003).

2.5.5.2. Hormonal Regulation of Metamorphosis in *Drosophila melanogaster*

Hormonal regulation of metamorphosis in *Drosophila* is similar to that described for other insects, with postembryonic development wholly dependent upon exposure of tissues to coordinated pulses of 20E, which, in turn, produce a coordinated cascade of gene expression (Riddiford, 1993; Truman and Riddiford, 2002). Cloning of the *Drosophila* ecdysone receptor (*EcR*) gene permitted the undertaking of studies of expression patterns of the receptor in tissues, including neurons and muscles (Koelle *et al*., 1991; Robinow *et al*., 1993; Talbot *et al*., 1993; Truman *et al*., 1994). Consistent with the results from *Manduca*, these studies have reinforced the view that ecdysteroid regulation of PCD in insects is typically a result of direct action of the steroid on the cells that are fated to die (Robinow *et al*., 1993).

2.5.5.3. PCD of Neurons during Early Development and Metamorphosis

In *Drosophila*, there are four periods of cell death in the nervous system: during mid to late embryogenesis, in late third instar larvae, in pupae during metamorphosis, and in the newly eclosed adult. The cell death that occurs during these stages permits the generation of a functional larval and adult nervous system by eliminating cells that are produced in excess, such as the embryonic midline glia, or cells with transient functions, such as larval abdominal ganglion neuroblasts (Kimura and Truman, 1990; Truman *et al*., 1993; Sonnenfeld and Jacobs, 1995a; Zhou *et al*., 1995). As in mammalian development, the extent of cell death in the developing *Drosophila* nervous system is profound: approximately two-thirds of all cells born within the embryonic CNS die before larval hatching (Abrams *et al*., 1993; White *et al*., 1994) (**Figure 8**).

The great extent of cell death in the *Drosophila* embryos suggests that this process is critical for early nervous system development. In this regard, mutations in several genes that are important for cell death result in hypertrophy of the embryonic, larval, or adult CNS, and these mutants can exhibit stage-specific lethality or sterility (Grether *et al*., 1995; Song *et al*. 1997; Zhou *et al*., 1997; Peterson *et al*., 2002). Interestingly, the removal of dead cells within the CNS is also apparently important for nervous system development, as mutants lacking functional macrophages exhibit disruptions in the normal architecture of the embryonic axon scaffold (Sears *et al*., 2003).

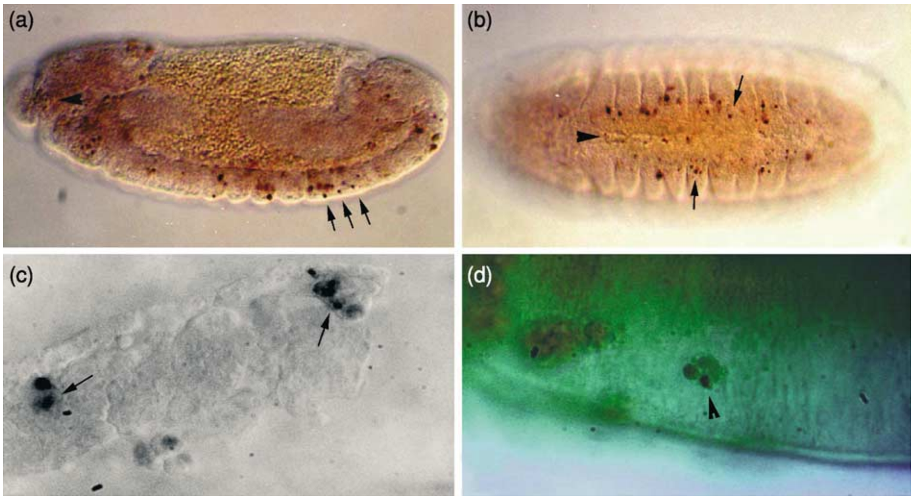

Figure 8 Detection of dying cells in *Drosophila* embryos. (a) Sagittal view of a stage 12 wild-type embryo analyzed via *in situ* nick translation to detect fragmented chromatin in dying cells. Note the prominent cell death in the retracting germ band (arrows). Significant cell death is also detected in the cephalic region of the embryo (arrowhead). Anterior is left and dorsal is up. (b) Ventral view of a stage 12 embryo labeled via *in situ* nick translation. Note the asymmetric pattern of dying cells in the neuroectoderm (arrows) on both sides of the CNS midline (arrowhead). Anterior is to left. (c) Section of tissue showing multiple labeled apoptotic bodies within phagocytic macrophages (arrows). (d) Ventral region of stage 16 embryo indicating an apoptotic body (arrowhead) engulfed by a circulating macrophage.

In contrast to the situation in the embryo, the proportion of neurons that die during the postembryonic period is much lower, and the widespread degeneration of larval tissues, characteristic of metamorphosis in flies, does not extend to the CNS. As in the *Manduca* model described above (see Section 2.5.4.3.1), most neurons of the larva persist rather than die, and the adult nervous system is, therefore, a composite structure of persisting neurons, born during embryogenesis, and adult-specific neurons. After pupariation, however, many dying neurons are observed in the ventral CNS in both thoracic and abdominal neuromeres (Truman *et al.*, 1993). The identity of most of these neurons has not been determined, with the exception of several motoneurons identified by retrograde fills of the T2 mesothoracic nerve (Consoulas *et al.*, 2002). The population of neurons that die at this metamorphic transition likely includes motoneurons that have lost their muscle targets, and interneurons in circuits for larval-specific behaviors. In addition, PCD of neuroblasts after pupariation marks the termination of postembryonic neurogenesis in the ventral nervous system (Truman and Bate, 1988; Truman *et al.*, 1993).

The death of neurons after adult eclosion has received more in-depth study than the neuronal deaths associated with pupariation (Kimura and Truman, 1990). Neurons dying at this time presumably include the motoneurons that innervate the abdominal muscles used during ecdysis and wing expansion (Truman *et al.*, 1993). Many features of posteclosion neuronal death in *Drosophila* mirror phenomena previously is described in the *Manduca* model. For example, neuronal death is delayed in newly eclosed flies that are forced to continue ecdysis behavior beyond the normal period (Kimura and Truman, 1990), as is the death of motoneurons in the abdominal ganglia of moths forced to dig after eclosion (Truman, 1983). Decapitation of flies at the time of eclosion results in inhibition of neuronal death in the ventral nervous system, similar to the sparing of MN-12 in *Manduca* by nerve cord transection (Kimura and Truman, 1990) (see Section 2.5.4.4).

Another major feature shared by the *Manduca* and *Drosophila* models of posteclosion neuronal death is its regulation by ecdysteroids. Treatment of both newly emerged flies and moths with ecdysteroids delays the PCD of neurons: only in the fly, however, can the molecular basis of this phenomenon be readily investigated (e.g., Baehrecke, 2000). In fact, the powerful molecular genetic approaches available in *Drosophila* make it possible to explore in detail the specific mechanisms that regulate cell survival in the developing nervous system. In addition to the continuing study of the posteclosion neuronal deaths initially described by Kimura and Truman (1990), this issue has been addressed using several distinct cellular systems, including the embryonic CNS midline, as well as embryonic and larval neuroblasts. In the following sections these

examples will be considered and the specific contributions that each has made toward the understanding of cell death regulation will be discussed.

2.5.5.3.1. Role of EcR in posteclosion neuronal death The *EcR* gene of *Drosophila* encodes three ecdysone receptor subunits: EcR-A, EcR-B1, and EcR-B2 (Talbot *et al.*, 1993). These receptor subunits share common DNA and ligand-binding domains, but have different N-terminal regions. EcR-A and EcR-B1 can be distinguished by monoclonal antibodies. The use of these antibodies to examine the expression of EcR isoforms in the metamorphosing *Drosophila* CNS revealed that a high level of expression of EcR-A is correlated with posteclosion PCD (Robinow *et al.*, 1993). Nearly 300 neurons, whose neuronal status was confirmed by double labeling with antibodies against EcR-A and ELAV (embryonic lethal, abnormal vision, a neuron-specific protein) in the ventral ganglia, displayed high levels of EcR-A-immunoreactivity. With rare exceptions, all EcR-A/ELAV-immunopositive neurons were absent from the ganglion 24 h after adult eclosion. Confocal microscopy of EcR-A-immunopositive neurons during day 1 of adult life revealed that these cells underwent PCD during this time. This study implies that EcR-A expression during the period of ecdysteroid decline, which accompanies the end of metamorphosis, is critical to the decision for these neurons to commit suicide.

Because nuclear hormone receptors such as EcR act as transcription factors, an important follow-up to the aforementioned studies is to determine the identity of genes that are regulated by ecdysteroids via the EcR-A. Obvious candidates are the *reaper*, *grim*, and *hid* genes, previously shown to be involved in the apoptotic pathway, now known to be indirect regulators of caspase activity by means of their ability to bind to inhibitors of apoptosis proteins (IAPs) (review: Hay, 2000) (see Section 2.5.5.4.1). When newly emerged adult flies were injected with 20E within 20 min of eclosion, the presence of the steroid blocked both PCD and the accumulation of *reaper* transcripts, normally seen in EcR-A-immunopositive neurons at this time (Robinow *et al.*, 1997). Neurons destined for death at this time were also demonstrated to accumulate *grim* but not *hid* transcripts.

The relationship of EcR-A to other examples of PCD in *Drosophila* and in insects, generally, remains to be determined. It is known that EcR-A and EcR-B1 have different tissue distributions during *Drosophila* metamorphosis (Talbot *et al.*, 1993), and that not all cells that express EcR-A will undergo PCD. However, at present there is no model to explain the tissue-specific distributions of the different isoforms. Expression of individual isoforms in a line of dominant-negative EcR mutants showed that EcR-A can support metamorphosis in numerous tissues, including the fat body, eye discs, salivary glands, and wing discs, but revealed no links that could be interpreted in relationship to PCD (Cherbas *et al.*, 2003).

2.5.5.4. Molecular Mechanisms of Neuronal Death

Most of the insights into the genetics of PCD in *Drosophila* have come from studies of embryonic development rather than metamorphosis. The key insights from studies on embryos, as they form the foundation for understanding control of postembryonic PCD are presented here.

2.5.5.4.1. The *Drosophila* cell death "machinery" Flies utilize a conserved cell death machinery that includes caspases, a Ced (cell death abnormal)-4/Apaf (apoptosome associated factor)-1 ortholog, and Ced-9/Bcl-2 protein family members (Tittel and Steller, 2000; Vernooy *et al.*, 2000) (**Table 1**). These proteins all have critical functions in apoptosis that were initially defined by studies in *C. elegans* (Horvitz *et al.*, 1994; Liu and Hengartner, 1999). In addition, however, several novel cell death regulators and cell survival mechanisms have been identified in flies.

Caspases are specialized members of the cysteine protease family that cleave aspartate or glutamate residues within enzymatic or structural substrate proteins to promote the dismantling of a cell (Hengartner, 2000). In *Drosophila*, there are seven caspases (**Table 1**), including three long prodomain initiator caspases, such as Dronc (*Drosophila* nedd2-like caspase; similar to caspase-9), and four

Apaf-1/Ced 4 family	Dark/HAC-1/Dapaf-1

short prodomain effector caspases, such as drICE (similar to caspase-3) and DCP-1 (death caspase1; similar to caspase-7). Loss-of-function mutations in *dcp-1* result in larval lethality and formation of melanotic tumors (Song *et al.*, 1997). The *Drosophila* Ced-4/Apaf-1 homolog is known as Dark (Drosophila apaf-1 related Killer)/HAC (homolog of apaf-1 and Ced-4)-1/Dapaf-1 and, like its worm and mammalian counterparts, associates with and promotes activation of long prodomain caspases (Kanuka *et al.*, 1999; Rodriguez *et al.*, 1999; Zhou *et al.*, 1999). Dark is expressed in dying cells and, interestingly, resembles its mammalian but not worm counterpart in that it contains WD repeats that can bind cytochrome *c*, and *dark* mutants exhibit decreased cell death in the embryonic CNS, hypertrophy of the larval CNS, and the formation of melanotic tumors.

Flies possess two Bcl-2 family members, drob (*Drosophila* ortholog of the Bcl-2 family)-1/debcl (death executioner Bcl-2 homolog)/Dborg (*Drosophila* Bcl-2 ortholog)-1/dbok and Buffy/Dborg-2, which both possess Bcl-2 homology (BH) domains BH1, BH2, and BH3 (Brachmann *et al.*, 2000; Colussi *et al.*, 2000; Igaki *et al.*, 2000; Zhang *et al.*, 2000). Both of these proteins resemble the proapoptotic mammalian Bok protein and act to promote apoptosis. Thus, unlike *C. elegans* and mammals, *Drosophila* does not appear to possess antiapoptotic Bcl-2 family members. This suggests that, both in terms of molecular and cellular complexity, *Drosophila* may prove to be a very useful system for bridging the gap that exists between the relatively simple nematode *C. elegans* and the more complex mammals. For example, in *C. elegans*, cell death eliminates approximately 10% of all cells, is governed largely by cell lineage, and is not required for organismal viability or fertility (Horvitz *et al.*, 1994; Liu and Hengartner, 1999). In contrast, in flies and mammals a much larger proportion of cells die, their survival is often governed by extrinsic signals, and normal progression of cell death programs is required for viability.

2.5.5.4.2. Role of IAP family proteins in PCD The Grim-Reaper proteins, initially identified in the first molecular genetic studies of PCD in *Drosophila*, all act upstream of caspases and their proapoptotic activities are blocked by the baculovirus caspase inhibitor, p35 (Grether *et al.*, 1995; Chen *et al.*, 1996; White *et al.*, 1996; Christich *et al.*, 2002; Srinivasula *et al.*, 2002; Wing *et al.*, 2002). Because the Grim-Reaper proteins do not share extensive homology to other proteins of known function, the mechanism through which they promote cell death was not immediately apparent. Elucidation of their actions was greatly advanced by the identification and analysis of DIAP1 and DIAP2, *Drosophila* members of the IAP family (Hay *et al.*, 1995). IAPs were first identified from the *Cydia pomonella* granulosis virus (Crook *et al.*, 1993); since then, a large number of viral and cellular IAPs have been identified that are potent death inhibitors (Deveraux and Reed, 1999; Miller, 1999; Hay, 2000). IAPs all contain one or more copies of a 70 amino acid baculovirus IAP repeat (BIR) domain, typically located in the central or N-terminal region of the protein. In addition, they also contain a 50 amino acid RING (Really Interesting New Gene) domain, generally situated towards the C-terminal region of the protein. The sequences of the BIR and RING domains resemble zinc fingers, and both serve as protein–protein interaction domains. The BIR domains and associated linker regions are required to block caspase activities, and association between the linker domain and caspases is strengthened by the BIR domain (Huang *et al.*, 2001). The RING domain possesses ubiquitin E3 ligase activity that can target bound caspases for polyubiquitination and degradation via the 26S proteasome (Suzuki *et al.*, 2001b; Wilson *et al.*, 2002). In addition, IAPs bound to caspases are also targeted themselves for proteasome-dependent proteolysis via the N-end rule pathway of protein turnover (Ditzel *et al.*, 2003). The turnover of caspases via the ubiquitin–proteasome pathway affords an efficient mechanism for the IAPs to reduce caspase levels, and the interplay between caspases and IAPs is a key determinant of cell survival. The levels of IAPs themselves are also under rigid regulation, as proapoptotic stimuli can result in IAP autoubiquitination and proteasome-dependent degradation, thus promoting cell death (Yang *et al.*, 2000; Yoo *et al.*, 2002). In *Drosophila*, DIAPs play a particularly critical role in cell survival; loss of *diap1* results in early embryonic lethality associated with massive ectopic cell death (Wang *et al.*, 1999; Goyal *et al.*, 2000; Lisi *et al.*, 2000).

Significantly, the BIR domains of DIAP1 bind both caspases and the Grim-Reaper proteins. In particular, the BIR2 domain of DIAP1 associates with the RHG motif/IBM of the Grim-Reaper proteins. Hid, Grim, and, presumably, Reaper utilize a conserved 7 amino acid stretch of the RHG motif/IBM (amino acids 2–8) to directly contact residues within the BIR2 domain (Wu *et al.*, 2001). Sickle also binds the BIR2 domain, but its RHG motif/IBM differs from that of Reaper, Hid, and Grim and only the first four residues make direct contacts (Srinivasula *et al.*, 2002). This association with Grim-Reaper proteins promotes cell death by

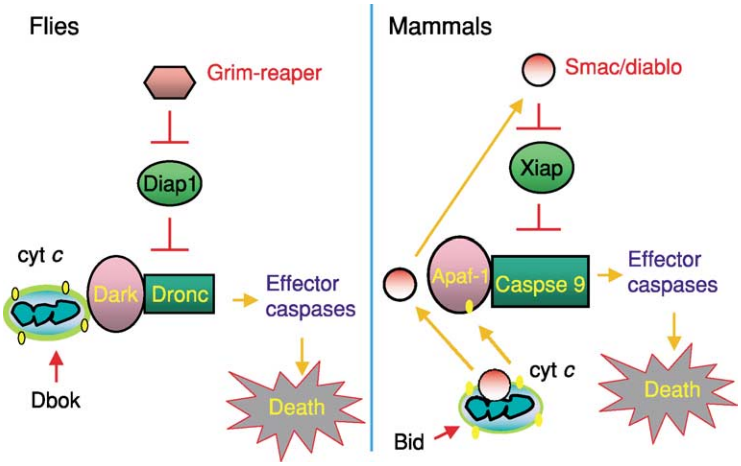

Figure 9 IAP inhibition is a conserved mechanism of regulation of apoptosis. In *Drosophila*, expression of the *grim-reaper* genes is activated in doomed cells, and the corresponding proteins bind to DIAP1 and block its ability to inhibit caspases. This results in active caspases that degrade cellular proteins to mediate apoptosis. In mammals, proapoptotic stimuli induce the release of Smac/Diablo as well as other proapoptotic factors, including cytochrome *c*, from the mitochondria. Cytoplasmic Smac/Diablo binds XIAP and represses its caspase-inhibitory actions, thereby promoting apoptosis. In both flies and mammals, the orthologous Dark and Apaf-1 proteins as well as proapoptotic members of the Ced-9/Bcl-2 family promote activation of initiator caspases.

blocking the ability of DIAP1 to bind and repress caspases. Thus, cell survival in *Drosophila* is controlled by a "double-inhibition" mechanism (**Figure 9**). In surviving cells, DIAP1 binds and inhibits caspase activities. In contrast, in cells signaled to die, the Grim-Reaper proteins are expressed and compete with caspases for DIAP1 binding. The displacement of caspases from DIAP1 results in proteolytically active molecules that promote cell death. Cell survival decisions are, therefore, determined to a large extent by the interactions between DIAP1, Grim-Reaper proteins, and caspases. Not surprisingly, the relative levels of these proteins within a cell are critical, and the effect of ectopic expression of these genes is highly dosage sensitive.

IAP inhibition is a conserved mechanism for regulating cell survival (**Figure 9**; review: Vaux and Silke, 2003). Thus, in mammals Smac (second mitochondria-derived activator of caspase)/Diablo is a mitochondrial protein that is released along with cytochrome *c* in dying cells (Du *et al*., 2000; Verhagen *et al*., 2000). Cytoplasmic Smac/Diablo associates with XIAP to prevent its binding and inhibition of caspase-9 (Chai *et al*., 2000; Liu *et al*., 2000). Strikingly, the binding of Smac/Diablo to IAPs is mediated through an N-terminal tetrapeptide sequence that is conserved in the Grim-Reaper RHG motif, indicating conserved modes of action for the fly and mammalian proteins (Chai *et al*., 2000; Srinivasula *et al*., 2000, 2002). Another mammalian IAP-inhibitor protein is the mitochondrial serine protease, Omi/HtrA2 (high temperature requirement protein A2), which also contains the conserved BIR-binding tetrapeptide at its N-terminus (Suzuki *et al*., 2001a; Hegde *et al*., 2002; Martins *et al*., 2002; van Loo *et al*., 2002; Verhagen *et al*., 2002). These similarities indicate that analysis of IAP inhibition mechanisms will provide insights into cell survival pathways in a wide range of species.

2.5.5.4.3. Evolutionary scenarios for the *grim-reaper* gene complex The small Reaper, Grim, and Sickle proteins are clearly ancestrally related, and the much larger Hid protein is also likely to share a common progenitor with them. Why are four related proteins needed to control DIAP1 inhibition and apoptosis, and how similar are the functions of these proteins? What proapoptotic activities, in addition to IAP inhibition, do the Grim-Reaper proteins share? Gene complexes can provide enhanced capabilities for a cell to finely control specific biological processes by providing gene products that exhibit overlapping yet distinct expression patterns and functions. Thus, multiple Hox proteins, for example, act together to permit elaboration of profound as well as subtle distinctions in cell and tissue types, and morphogenesis, along a major body axis (see **Chapter 1.8**). Presumably, the existence of the *reaper*, *hid*, *grim*, and *sickle* genes enables cells to control apoptosis with the exquisite specificity and efficiency that are required for developmental and physiological processes. The Grim-Reaper proteins do exhibit differences in their cell death-inducing abilities in developing tissues (Chen *et al*., 1996; Wing *et al*., 1998b, 2002), suggesting that they may have distinct abilities to interact with

DIAPs and promote apoptosis. In addition, gene expression studies as well as analysis of loss-of-function and gain-of-function mutants have indicated that these genes exhibit overlapping yet distinct patterns of expression and nonredundant cell killing activities (Grether *et al*., 1995; Robinow *et al*., 1997; Zhou *et al*., 1997; Wing *et al*., 1998b, 2002; Draizen *et al*., 1999). Presumably, each individual Grim-Reaper protein provides a unique capability to promote apoptosis and, together, these proteins permit a more complex control of apoptosis patterns than would be afforded by a single protein.

Interestingly, while the *grim-reaper* genes are essential cell death activators in *Drosophila*, *bona fide* structural homologs have so far been identified only in other *Drosophila* species. Thus, a *reaper* ortholog was described in *D. simulans* (White *et al*., 1994), and each *grim-reaper* gene is conserved in *D. pseudoobscura*. However, clear cut *grim-reaper* orthologs have not been identified from any other species, including the mosquito *Anopheles gambiae*. Therefore, the proapoptotic properties of Grim-Reaper proteins may have evolved only during divergence within the insect lineage. Finally, while the RHG motif/IBM has well-defined functions in IAP inhibition, the activities of the conserved Trp block/GH3 domain are less clear. The Trp block/GH3 domain appears to be important for mitochondrial actions of Grim and Reaper (Claveria *et al*., 2002; Olson *et al*., 2003), and may also be involved in interactions with other apoptosis regulators, such as Scythe, a large protein with a ubiquitin-like domain at its N-terminus (Thress *et al*., 1998). Alternatively, the Trp block/GH3 domain could be important for Reaper and Grim to act as general translational inhibitors (Holley *et al*., 2002; Yoo *et al*., 2002), and may promote cell death by favoring the accumulation of long-lived caspases versus less stable IAPs. Interestingly, the Trp block/GH3 domain, which shares sequence similarity to a nonstructural protein from some insect bunyaviruses (J.R. Nambu unpublished data), may also act to repress translation and promote cell death (Bridgen *et al*., 2001).

2.5.5.4.4. Regulation of embryonic glial cell survival One important mechanism for regulating the survival of neurons and glia within the developing vertebrate nervous system involves the actions of trophic factors (Raff *et al*., 1993). These prosurvival molecules are synthesized in restricted amounts by target tissues, and permit winnowing of innervating cells to ensure appropriate matching of interacting cell populations. Both neuron and glial cell types can either provide or respond to trophic signaling.

In *Drosophila*, interactions between neurons and glia are also important for cell survival (Booth *et al*., 2000; Kinrade *et al*., 2001), and recent studies have revealed that trophic mechanisms regulate cell survival in the developing CNS. Specifically, members of the epidermal growth factor (EGF) family of proteins have been shown to act as neuron-derived glial survival factors (Hidalgo *et al*., 2001; Bergmann *et al*., 2002).

Approximately 10% of all cells within the *Drosophila* nervous system are glia, and these cells provide critical functions in neuronal homeostasis, axonogenesis, and removal of cellular debris (Jones, 2001; Klambt *et al*., 2001). Among the best-characterized glial cells are the embryonic longitudinal and midline glia of the CNS. In both these lineages, cells undergo extensive apoptosis during embryogenesis (Sonnenfeld and Jacobs, 1995a; Zhou *et al*., 1995; Kinrade *et al*., 2001) (**Figure 10**). The selective survival of subsets of these cell populations is governed by trophic actions of EGF-related ligands and activation of the Ras/MAP (rat sarcoma/mitogen activated protein) kinase pathway via the EGF receptor homolog (EGFR).

During embryogenesis, a single, laterally positioned glioblast precursor gives rise to approximately 10 longitudinal glia in each hemisegment of the ventral nerve cord. These glial cells play a critical role in the formation of the longitudinal axon bundles; they migrate medially, contact pioneer longitudinal axons, and ultimately ensheathe the longitudinal nerve bundles (Hidalgo and Booth, 2000) (see **Chapter 1.10**). Coinciding with the onset of axon/glial contact, many of the glia undergo apoptosis (Kinrade *et al*., 2001), suggesting that, as the glia contact the axons, they become dependent upon them for survival. Consistent with this notion, ablation of pioneer and other neurons results in a decrease in longitudinal glia (Hidalgo *et al*., 2001). Thus, apoptosis determines the final numbers of longitudinal glia during embryogenesis, and axon-derived factors are required for longitudinal glial survival. One of these factors is Vein (Vn), a *Drosophila* neuregulin homolog that contains both an IgG domain and EGF domain (Schnepp *et al*., 1996). The *vein* gene is expressed in a small subset of neurons within the embryonic CNS, including the midline precursor 2 (MP2) pioneer neurons as well as the Ventral Unpaired Median (VUM) neurons of the CNS midline (Hidalgo *et al*., 2001) (see **Chapters 1.10** and **2.3**). Gene *vein* mutants exhibit ectopic apoptosis of longitudinal glial cells, and ectopic apoptosis also results from RNAi-mediated loss of *vein* function in either all neurons or the MP2 neurons (Hidalgo *et al*., 2001).

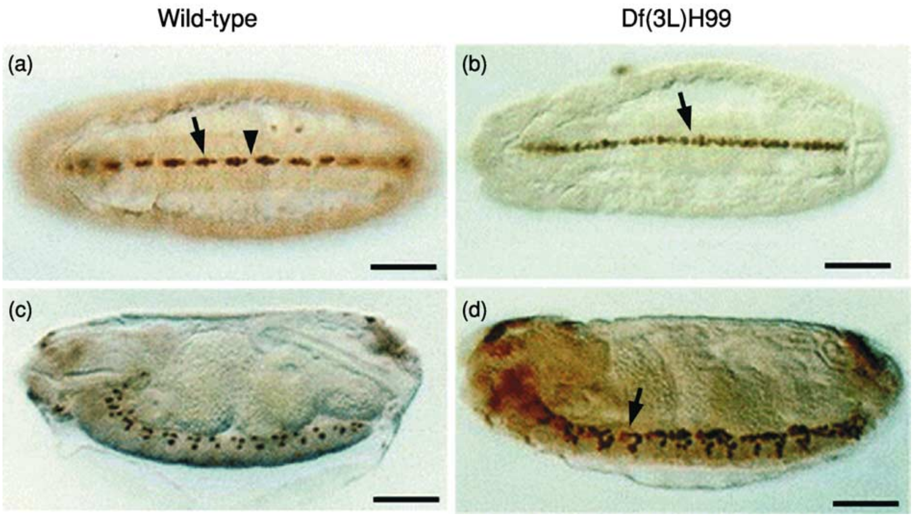

Figure 10 The embryonic CNS midline glia undergo developmental apoptosis. Embryos carrying a P[1.0slit-lacZ] transgene were immunostained with anti-β-galactosidase to detect the CNS midline glia. (a, c) In wild-type embryos (stages 15 and 16, respectively), there are approximately three midline glia per segment within the ventral nerve cord (arrow in a). The arrowhead in (a) points to the separation between two adjacent segmental clusters of midline glia that are eliminated with advanced development (c). (b, d) In Df(3L)H99 mutant embryos (stages 15 and 16, respectively), which lack *reaper*, *hid*, and *grim*, there is a blockade of apoptosis and accumulation of excess midline glia (arrow in b). The rescued midline glial cells accumulate at the dorsal surface of the ventral nerve cord (arrow in d).

Vein is a secreted ligand for the *Drosophila* EGFR receptor homolog (EGFR), and EGFR-mediated activation of the Ras/MAP kinase pathway is essential for longitduinal glial cell survival (Hidalgo *et al.*, 2001). The EGFR is transiently expressed in a subset of longitudinal glia, suggesting that Vein is secreted from axons to promote survival of longitudinal glial cells. Thus, Vein functions similarly to vertebrate neuregulins by providing axon-derived trophic support for developing glial cells via activation of receptor tyrosine kinase signaling pathways.

Another EGF family member, the transforming growth factor alpha (TGF-α) homolog Spitz (Spi), acts as a trophic factor to promote survival of the CNS midline glia (Bergmann *et al.*, 2002).

The midline glia are essential for proper formation of the axon scaffold, as migrating midline glia contact, separate, and ultimately ensheathe the anterior and posterior axon commisures (Klambt *et al.*, 1991). They synthesize several axon guidance factors such as D-Netrin (Net), Commissureless (Comm), and Slit (Sli) that control the crossing and recrossing of commisural axons (Jacobs, 2000; Kaprielian *et al.*, 2000).

Ultrastructural and genetic analyses indicate that the midline glia undergo apoptosis, which reduces their number from an initial set of nine cells to three cells in each segment of the mature ventral nerve cord (Sonnenfeld and Jacobs, 1995a; Zhou *et al.*, 1995). This apoptosis is dependent upon caspases and the actions of multiple Grim-Reaper proteins; loss of *reaper*, *hid*, and *grim* blocks all midline glial cell death and results in the survival of the nine midline glia per segment. The loss of *hid* and *grim* results in approximately seven to eight midline glia per segment, while the loss of *hid* alone results in six midline glia (Zhou *et al.*, 1997; Bergmann *et al.*, 2002). Thus, *hid* is required for the death of three midline glia and *reaper* and *grim* are together essential for the death of the other three midline glia.

Hid activities in the midline glia are regulated by proteins in the EGF signaling pathway, such as Spitz and EGFR (Bergmann *et al.*, 1998, 2002; Kurada and White, 1998). Both Spitz and EGFR are required for midline glial differentiation and survival, which, in turn, are essential for proper elaboration of the anterior and posterior commissures (Klambt *et al.*, 1991; Dong and Jacobs, 1997; Bergmann *et al.*, 2002). The loss of midline glia in *spitz* mutants is rescued in *spitz*; *hid* double mutants, implying that the proapoptotic functions of Hid are normally opposed by the prosurvival functions of Spitz.

The midline glia are normally in close contact with commissural axons, suggesting that glial–axon contact may be important for midline glial cell survival. Consistent with this notion, in *commissureless* mutants where the commissures fail to form, the isolated midline glial cells that fail to contact axons undergo apoptosis (Sonnenfeld and Jacobs, 1995a). The Spitz protein appears to be the axon-derived trophic factor required for midline

glial survival (Bergmann *et al*., 2002). The loss of midline glia in *spitz* mutants is rescued by targeted expression of the transmembrane Spitz precusor protein in commissural neurons, and the precise number of surviving midline glia can be modulated by controlling the levels of Spitz activity (Bergmann *et al*., 2002). The model that has emerged is that axon-derived Spitz protein signals the midline glia via EGFR, resulting in activation of the Ras/MAP kinase pathway. Hid activity is subsequently down-regulated via phosphorylation, which permits midline glial survival. Taken together, the actions of Vein in the longitudinal glia and Spitz in the midline glia indicate that trophic survival mechanisms are utilized to match the sizes of interacting populations of neurons and glia in invertebrates as well as vertebrates.

2.5.5.4.5. Regulation of cell survival by cell intrinsic mechanisms in sensory neuron lineages In *C. elegans*, cell lineage controls the pattern of cell survival, and the identity of each doomed cell can be determined by location, birth date, and gene expression patterns (Horvitz *et al*., 1994; Liu and Hengartner, 1999). In flies, stereotyped lineages within the developing CNS also undergo cell death (Bossing *et al*., 1996; Schmidt *et al*., 1997), and the question of how cell lineage controls cell survival decisions has been addressed in the developing peripheral nervous system (**Figure 11**). In particular, the ventral multidendritic sensory neuron 1a (vmd1a), which expresses the Cut (Ct) protein, is present in a cluster of five multidendritic (md) neurons in the ventral region of abdominal segments A1–A7

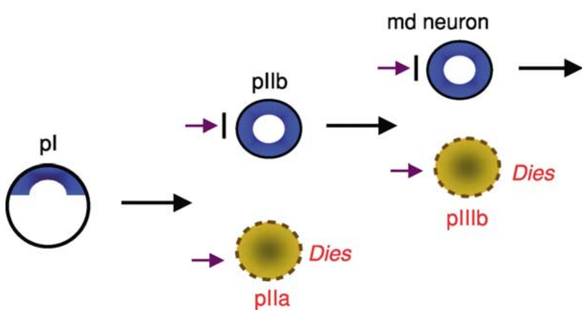

Figure 11 A model for the control of cell survival in the *Drosophila* vmdl sensory neuron lineage. The pI precursor cell exhibits asymmetric distribution of the Numb protein (blue). Upon division (black arrow) of pI, Numb becomes partitioned into the pIIb but not the pIIa daughter cell. Numb inhibits (black bar) the proapoptotic effects of Notch signaling (purple arrows) in the pIIb cell, which survives and divides to give rise to a Numb-positive multidendritic (md) neuron and a pIIIb daughter cell. As a result of Notch signaling that occurs in Numb-negative pIIa and pIIIb cells, the apoptosis activators Reaper and Grim are expressed (orange), resulting in caspase activation and apoptosis (brown and dashed line).

(Orgogozo *et al*., 2002). The vmd1a neuron is produced by two asymmetric divisions of a single sensory organ primary precursor cell (pI). The pI cell divides to generate a pIIa and pIIb progeny, one of which, pIIa, undergoes apoptosis. The pIIb cell divides again to generate the md neuron and a pIIIb cell, which also dies. Interestingly, the Numb protein, which is a cell fate determinant (Hirata *et al*., 1995; Knobloich *et al*., 1995; Spana *et al*., 1995), segregates asymmetrically into the daughter cells during both of these divisions. In both cases, Numb is detected in the surviving cell and is not present in the daughter cell that undergoes apoptosis. In addition, during the asymmetric division of the pIIb cell, the Prospero (Pros) protein also segregates into the surviving daughter cell. In contrast, the cell death activators Reaper and Grim, but not Hid, are expressed in the pIIa and pIIIb cells, which die. In embryos where cell death is blocked, an ectopic sensory (es) organ is detected, which contains four Cut-expressing cells. These include an ectopic shaft/socket and neuron/sheath cell pairs that are similar to the md–es lineage, where the pIIa and PIIIb cells do not die. Thus, in the absence of cell death, the vmd1a lineage is transformed into an md–es lineage. Cell death is, therefore, used to refine the sensory organ structures by eliminating cells that would otherwise give rise to additional cell types and morphological structures.

Mutants of the *numb* gene exhibit ectopic *reaper* or *grim* gene transcription in the progeny of the vmd1a pI daughter cells, and both daughter cells undergo apoptosis without giving rise to any Cut-expressing progeny. In contrast, ectopic Numb expression in the pI daughter cells results in duplication of md neuron and pIIIb cells. The Numb protein contains a zinc finger and a phosphotyrosine binding domain. Numb directly associates with Notch (N) and interferes with Notch signaling (Guo *et al*., 1996; Spana and Doe, 1996). This suggests that the death of cells in the vmd1a lineage is promoted by Notch, and that Numb acts to block Notch proapoptotic signaling (**Figure 11**). Consistent with this notion, ectopic expression of activated Notch, Nintra (Notch intracellular), was shown to promote the death of the pIIb cell when expressed during the period of pI cell division. Ectopic expression of *reaper* and *grim* was also detected, indicating that the effects of Nintra were similar to those observed for *numb* mutants. Therefore, in the vmd1a lineage, the distribution of Numb protein is critical for determining the survival of progeny cells. Daughter cells that inherit Numb are able to repress Notch-mediated activation of *reaper* and *grim* transcription, and subsequent apoptosis (**Figure 11**). This

appears to be a conserved mechanism of cell death during neural differentiation, as asymmetric distribution of the Numb protein also governs survival of the progeny from the embryonic neuroblast NB7-3 by inhibiting the proapoptotic actions of Notch signaling (Lundell *et al*., 2003).

2.5.5.4.6. Control of neuron number by neuroblast apoptosis In the *Drosophila* embryonic CNS, approximately 30 neuroblasts are formed in each segment that divide asymmetrically to generate a smaller ganglion mother cell, which divides once to give rise to two post-mitotic neurons (Goodman and Doe, 1993) (see **Chapters 1.10**, **1.12**, and **2.3**). The neurons that form during embryogenesis give rise to the larval nervous system. Generation of the adult nervous system requires the proliferation and differentiation of larval neuroblasts (see **Chapters 1.11** and **2.3**). Strikingly, the number of larval neuroblasts varies dramatically along the anterior–posterior axis. Thus, thoracic segments retain about 23 of the 30 neuroblasts generated during embryogenesis, while the abdominal segments retain only three embryonic neuroblasts (Truman *et al*., 1993). Abdominal and thoracic neuroblasts also differ in their proliferative properties, as thoracic neuroblasts divide for 4 days and produce approximately 100 cells, while abdominal neuroblasts divide for only 30 h and generate 4–12 cells.

The rapid cessation of abdominal neuroblast cell division is brought about by their elimination via apoptosis midway through the third larval instar. In contrast, the thoracic neuroblasts do not undergo a stage-specific cell death. Abdominal neuroblast apoptosis requires the actions of *reaper*, *hid*, and *grim* and, in Df(3L)H99 mutants, there is an accumulation of ectopic abdominal neurons (Bello *et al*., 2003). Interestingly, the rescued neuroblasts continue to proliferate and give rise to ectopic neural progeny. Reaper appears to be a key player in this process as *reaper* mutants also result in a survival of normally doomed abdominal neuroblasts, and *reaper* mutant flies exhibit a hypertrophied abdominal ganglia and male infertility (Peterson *et al*., 2002). Thus, the programmed death of abdominal neuroblasts directly controls their reproductive capacity and number of progeny.

The segment-specific differences in neuroblast survival are controlled by the homeotic selector protein, Abdominal A (AbdA), which, along with Ultrabithorax (Ubx) and AbdB, govern abdominal segment identities (Lewis, 1978; Sanchez-Herrero *et al*., 1985). Loss of AbdA function results in increased numbers of abdominal neuroblast progeny, and the mutant abdominal neuroblasts also survive longer than the wild type (Bello *et al*., 2003). In addition, ectopic expression of AbdA is sufficient to induce premature cell death of thoracic neuroblasts. This death requires the *grim-reaper* genes and is blocked in a Df(3L)H99 mutant background. Interestingly, expression of either the Antennapedia (Antp) or Ubx homeodomain proteins also induces thoracic neuroblast apoptosis, implying that a very precise control of homeodomain protein expression is necessary for appropriate cell survival patterns. Indeed, while postmitotic progeny of thoracic neuroblasts do express Ubx or Antp, the neuroblasts themselves do not.

The death of the three abdominal neuroblasts occurs in a highly synchronized fashion, and this timing appears to be the direct result of a very tight burst of AbdA expression specifically within the neuroblasts, but not in the ganglion mother cells or neurons, during the third larval instar (Bello *et al*., 2003). Thus, the timing of AbdA expression is a critical determinant of cell survival. Indeed, precocious AbdA expression results in a smaller number of neural progeny and early death of the neuroblasts.

One important issue that remains unresolved is how the transient and specific expression of AbdA is controlled in abdominal neuroblasts. Is there a transient extrinsic signal that cues the abdominal neuroblasts to activate AbdA expression, or do the neuroblasts possess an intrinsic counting mechanism that permits them to keep track of the number of divisions they undergo? Elucidation of these questions will provide a molecular mechanism to directly link Hox gene actions and segment-specific differences in the nervous system.

2.5.5.4.7. Removal of dying cells is important for proper organization of the embryonic CNS The role of phagocytic cells in PCD is described above (see Section 2.5.2.1). In *Drosophila*, specialized macrophages differentiate from hemocyte precursors that are derived from head mesoderm tissue (Tepass *et al*., 1994). Macrophages migrate throughout the body cavity, along several stereotypic routes, and rely on guidance cues that include PVR (PDGF and VEGF receptor-related), a member of the platelet-derived and vascular endothelial growth factor (PDGF/VEGF) receptor tyrosine kinase family (Cho *et al*., 2002). While macrophages are excluded from the CNS itself, they engulf dying cells that are expelled from the nervous system (Sonnenfeld and Jacobs, 1995b).

Because of their intimate association with the CNS, it was of interest to determine if macrophage functions might be important for nervous

system development. Mutations that disrupt macrophage development, migration, or engulfment abilities produce mutants exhibiting disruptions in the normal architecture of the axon scaffold (Sears *et al.*, 2003). Specifically, the junctures between the longitudinal axon connectives and anterior and posterior commissures in each segment exhibit reduced separation and a rounded appearance. In addition, many CNS glia were misplaced and accumulated along the ventral midline. Thus, the efficient removal of dead and dying cells from the CNS is important for the elaboration of the axon scaffold and the glial cell positions within the CNS. In contrast, mutants that lack macrophages still exhibit essentially normal patterns of cell death, indicating that, although macrophages sculpt the CNS, they do not have a major role in promoting apoptosis (Tepass *et al.*, 1994; Sears *et al.*, 2003).

2.5.5.5. PCD of Muscles during Metamorphosis

As is the case in *Manduca*, fruit flies undergo extensive death of abdominal muscles after adult eclosion (Miller, 1950); the muscles that die at this time appear to be larval muscles that persisted during metamorphosis (Kimura and Truman, 1990). These persisting larval muscles are a very small subset of all larval muscles, the majority of which undergo PCD at the onset of metamorphosis (Currie and Bate, 1991). In the abdomen, only a few muscles survive; although some of the persisting muscles continue to function during pupal life and adult emergence, others persist only to provide a template for adult myogenesis (Broadie and Bate, 1991; Bate, 1993) (see **Chapters 2.1–2.3**). Some of these new muscles, including the male-specific muscle, may be dependent upon innervation for differentiation and survival (Bate, 1993). Phagocytosis of degenerated (also referred to as histolyzed) muscle is a feature of the larval–pupal transition in *Drosophila* (Crossley, 1978; Bate, 1993), but phagocytic cells do not appear to be associated with dying muscles after adult eclosion, as has also been reported for *Manduca* ISMs (Kimura and Truman, 1990; Jones and Schwartz, 2001).

In contrast to the situation in *Manduca*, PCD of muscles during metamorphosis in *Drosophila* has not been a focus of research, and at present it is not possible to say more than that, most likely, the typical complement of cell death genes is expressed in dying muscle in a steroid-regulated manner. As described above (see Section 2.5.4.5.3), muscle abnormalities have been observed in transgenic *Drosophila* created to study genes identified in a screen of dying moth ISMs. Interest in the study of PCD of muscle in *Drosophila* may be stimulated by the development of fly muscle models for human diseases, such as spinal muscular atrophy (Chan *et al.*, 2003) and Parkinson's disease (Greene *et al.*, 2003). The latter studies are particularly interesting, because flies, with loss of function mutations in the *parkin* (*park*) gene, which encodes a ubiquitin E3 ligase, are associated with mitochondrial abnormalities: the involvement of ubiquitin regulation of proteolysis and the mitochondrial abnormalities suggests an important relationship between pathology and PCD in normal development (Haas *et al.*, 1995).

2.5.6. Future Directions

Many unanswered questions remain concerning PCD of the insect nerve and muscle during metamorphosis. A partial list includes the following:

- Are all deaths of neurons during insect metamorphosis controlled by ecdysteroids?
- What deaths of insect neurons during metamorphosis are apoptotic, if any? Why do different cell populations (or the same cell populations studied at different stages of development) display different forms of PCD?
- What is the relationship between apoptosis in the insect embryo and PCD during metamorphosis?
- Faced with evidence that some genes associated with death in insect muscles are not associated with death in insect neurons, can we conclude that there are tissue-specific death genes?
- What is the source of the segment specificity of PCD at the metamorphic transitions? Can we generalize some of the mechanisms that account for segment specificity in neuroblast apoptosis to postembryonic cell deaths?
- Why is phagocytosis not evident in many examples of metamorphic PCD?
- Since death-associated transcripts accumulate in the ISMs hours before their proteins can be detected or death begins, what molecular event triggers translation?

Answers to these questions are likely to expand our understanding of developmental PCD over a broad taxonomic range.

2.6 Heart Development and Function

R Bodmer and R J Wessells,
The Burnham Institute, La Jolla, CA, USA
E C Johnson, Wake Forest University,
Winston-Salem, NC, USA
H Dowse, University of Maine, Orono, ME, USA

2.6.1. Introduction

The heart in vertebrates is the central organ of a functional organism. In insects, the functional importance of a heart is less evident, since they do not have an elaborate vascular system and transport of oxygen is carried out by the highly branched tracheal system. Nevertheless, the molecular components and basic control mechanisms of how the heart develops and how it functions are strikingly similar in vertebrates, chordates, and insects (Bodmer, 1995; Harvey, 1996; Bodmer and Venkatesh, 1998; Cripps and Olson, 2002; Zaffran and Frasch, 2002; Holland *et al*., 2003). Therefore, it is likely that an ancestral "heart" existed before the split of insects and chordates during evolution. Even nematodes, which do not have a heart, employ some of the same key genes that normally control formation of the cardiac progenitors (Haun *et al*., 1998). These genes control the formation of the pharyngeal muscle, which is another mesodermally derived organ with recurrent waves of contraction and relaxation. Therefore, it may be that the control of rhythmical movements, such as that of the pharynx and the heart, has a common evolutionary origin. Heart research with evolutionary distant insects may shed more light on these relationships. The availability of the whole genome sequence from the dipteran *Drosophila* and the mosquito *Anopheles* will greatly facilitate such efforts.

In Section 2.6.2, the molecular genetic basis of heart development in *Drosophila*, the only insect in which this process has been studied in detail and at the molecular level, is reviewed. Because of the conservation of the basic mechanisms that regulate the specification of the heart, many of the insights gained from *Drosophila* will undoubtedly also be applicable to other insects, and hopefully spur research in suitable (i.e., larger) species, where studying embryological events may be advantageous.

In Section 2.6.3, the functional properties of the insect heart by drawing on information from a variety of insects have been discussed. As in all hearts, the physiological control of the heart beat in frequency and vigor is of most critical importance, and thus the cardiac pacemaker is most extensively discussed. Recent advances in *Drosophila* begin to shed light on the molecular control of the pacemaker and other properties of heart function.

Finally, in Section 2.6.4 recent studies in heart function during the aging process are reviewed. Again, conserved molecular mechanisms have emerged that regulate lifespan from nematodes to mammals (Tatar *et al*., 2003). In *Drosophila*, and probably in other insects as well as in vertebrates, genes controlling the rate of aging also seem to operate specifically in determining the efficacy of heart function. Thus, as insects have been the key to understanding global genetic mechanisms of development, they may provide us again with the opportunity

of gaining mechanistic insights into the relationship of aging and (heart) organ function.

2.6.2. Heart Development

2.6.2.1. Embryology of Heart Formation

As in other insects, the heart of *Drosophila* is a linear tubular structure that forms at the dorsal midline of the embryo (**Figure 1**). In an open circulatory system, the heart pumps the hemolymph through the larval and adult body cavity (Miller, 1950; Rizki, 1978). Studies in *Drosophila* and another dipteran, *Calliphora*, suggest that during metamorphosis, the heart persists but is substantially remodeled (Jensen, 1973; Curtis *et al*., 1999; Molina and Cripps, 2001). In larvae, a simple valve is located in the middle of the heart (Rizki, 1978), which separates the narrower anterior portion, the aorta, from the wider posterior part, the heart proper and cardiac pacemaker, which are located in the posterior abdominal segments (see Section 2.6.4). This posterior larval heart also contains three segmental pairs of inlet valves, the ostia, which express and require the COUP transcription factor encoded by *seven-up* (*svp*) (Rizki 1978; Gajewski *et al*., 2000; Lo and Frasch, 2001, Molina and Cripps, 2001; Ponzielli *et al*., 2002). After remodeling to the adult heart during metamorphosis, which results in histolysis of the heart portion, four new pairs of *svp* expressing ostia differentiate in the anterior portion of the abdomen (Molina and Cripps, 2001). The larval heart in *Drosophila* consists of two major cell types: the inner two rows are contractile muscle cells (myocardial cells), expressing the muscle MADS-box transcription factor Dmef2, flanked on each side by rows of pericardial cells (**Figure 1**). The myocardial cells are crescent shaped and face each other, thereby forming a central cavity, the lumen of the heart (**Figure 1**). The heart is attached to the epidermis by small skeletal muscles, the alary muscles, which suspend it along the dorsal midline. In contrast to insects, the vertebrate heart is a more complex, asymmetrically looped organ containing multiple valves, chambers, and tissue layers (see Rosenthal and Harvey, 1999).

2.6.2.1.1. Mesodermal movements and subdivision The knowledge on the embryology, let alone genetics, of heart formation in insects other than *Drosophila* is scarce (e.g., Seidel *et al*., 1940), thus the focus is on the fruit fly, *Drosophila melanogaster* ("Vinegar fly"). During gastrulation of *Drosophila* embryos, the ventral third portion of the blastoderm embryo, the presumptive mesoderm, invaginates in a furrow along the ventral midline and initially localizes internally as a ventral mass of cells. This mesodermal mass then flattens and spreads dorsally by cell migration to form a morphologically uniform monolayer of cells in close contact with the ectoderm (Leptin and Grunewald, 1990). At the same time, the long germ band folds over and extends anteriorly, so that the posterior end of the embryo comes in contact with the head region (**Figure 2a**). When the mesodermal layer reaches the dorsal edge of the ectoderm, the first subdivision occurs into dorsal mesoderm and ventral mesoderm, as defined by marker gene expression (see below). After that, the mesoderm undergoes the first discernible morphological subdivisions. The dorsal mesoderm segregates into two layers: the outer, dorsal somatic mesoderm giving rise mostly to skeletal muscles, and the inner, visceral mesoderm, which assumes the form of a distinct and continuous epithelial layer (Borkowski *et al*., 1995). Then, the progenitors of the heart emerge from the dorsal edge of this outer mesodermal layer, termed the cardiac mesoderm (**Figure 2**; Bodmer *et al*., 1990). At that time (early to mid stage 11), the first cardiac

specific marker genes are expressed in the presumptive heart field (see below). The fat body and gonadal mesoderm are also specified from the dorsal mesoderm (Azpiazu *et al*., 1996; Riechmann *et al*., 1997; **Chapters 1.2** and **2.9**).

2.6.2.1.2. Heart morphogenesis Initially, the bilaterally symmetrical heart primodia are only distinguishable by marker gene expression. After stage 12, the germ band retracts again (Campos-Ortega and Hartenstein, 1997), leaving the dorsal side of the embryo open with a thin sheath of extraembryonic tissue, the amnioserosa, covering the yolk sac. After germ band retraction, the two rows of cardiac mesoderm move towards the dorsal midline (**Figure 2c**) by following the ectoderm, which precedes the mesodermal movements during this process of dorsal closure (Reed *et al*., 2001). Prior to the joining of the bilateral symmetrical primordium into a heart tube beneath the dorsal midline, the myocardial progenitors take on an epithelial character with distinct basal (ventral) and apical (dorsal) polarity (Rugendorff *et al*., 1994; Chartier *et al*., 2002). Cell shape and subcellular changes of the prospective myocardial cells during cardiac morphogenesis have not yet been studied in detail, and the molecular–genetic basis of orderly alignment of myocardial cells and subsequent formation of the lumen remains largely unexplored.

It has been proposed that the process of heart tube assembly is reminiscent of the assembly of blood vessels in vertebrates (Rugendorff *et al*., 1994). In an alternative model, it has been suggested that the embryological origin and the overall process of heart tube formation from bilateral mesodermal primordia most distal to the start of gastrulation is equivalent to that of vertebrates, given the inversion of dorsal–ventral axis (Bodmer, 1995). Moreover, many of the molecular determinants of cardiogenesis have conserved roles in the animal kingdom (see below; reviews: Harvey, 1996; Bodmer and Venkatesh, 1998; Lockwood *et al*., 2001; Cripps and Olson, 2002; Zaffran and Frasch, 2002). One can imagine that these two models are not mutually exclusive and may have many elements in common, since both blood vessels and hearts form a lumen and are able to contract. Insects lack a closed circulatory system, which in vertebrates is accomplished by a seamless endothelial connection between the vertebrate specific endocardium and blood vessels (Fishman and Chien, 1997); and the insect hearts remain linear, unlike their vertebrate counterparts. Thus, it is conceivable that hearts and blood vessels share a common ancestor, which may still be manifest in the insect heart. Moreover, other rhythmically contracting organs such as the pharynx have been proposed to share a common ancestor with hearts, based on interchangeable homologous molecular determinants that function not only in the vertebrate and insect heart (see below), but are also required to build the nematode's pharynx (Haun *et al*., 1998).

2.6.2.1.3. Cardiac cell types and lineages Although the mechanisms and detailed events of cardiac morphogenesis, cell polarity changes, and lumen formation remain to be elucidated, the lineages that contribute to the cell types that form the heart tube and surrounding pericardial cells have been studied in some detail (**Figure 3**; Carmena *et al*., 1998; Park *et al*., 1998; Ward and Skeath, 2000; Alvarez *et al*., 2003; Han and Bodmer, 2003). Within the emerging cardiac anlagen at the dorsal mesodermal edge (**Figure 2a**), sets of progenitors express distinct combinations of transcription factors, which are thought to be involved in conferring the appropriate differentiation pathway to these cardiac precursors (see below; Ward and Skeath, 2000; Han *et al*., 2002; Jagla *et al*., 2002; Klinedinst and Bodmer, 2003). These progenitors also undergo defined and segmentally repeated patterns of lineage divisions, which generate a diversity of cardiac cell types (Ward and Skeath, 2000; Alvarez *et al*., 2003; Han and Bodmer, 2003). As outlined below, some of the heart precursors divide symmetrically, whereas others undergo stereotyped asymmetric cell divisions.

2.6.2.1.3.1. Cell-type specific markers The cardiac progenitors are first distinguishable from other mesodermal cells at mid stage 11, when most if not all express a NK-type homeobox transcription factor encoded by the *tinman* (tin) gene, as a two to three cell-wide chain of dorsal mesodermal cells

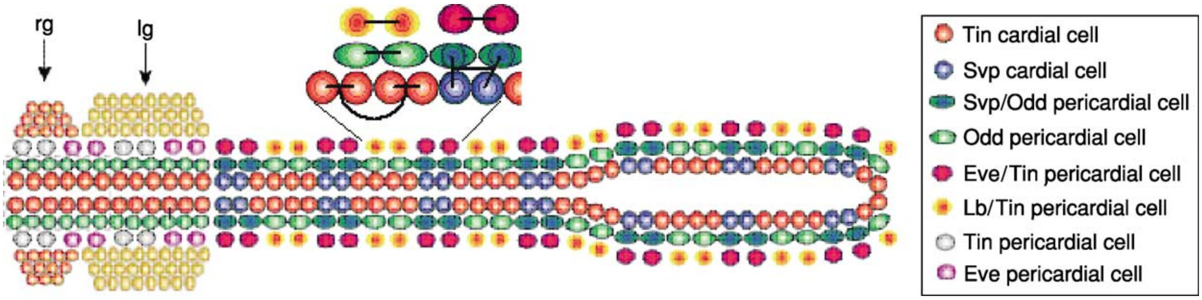

Figure 3 Diagrammatic representation of myocardial and pericardial cell types associated with the heart. rg, ring gland; lg, lymph gland. Enlarged half segment diagram (upper middle): back bars connecting cells indicate lineage relationships. Bar of arc connecting two pairs of siblings indicate higher order lineage relationships. (Diagram kindly supplied by Krista Golden.)

spanning from the third thoracic segment (T3) to the eighth abdominal segment (A8) (**Figure 2**; Bodmer *et al.*, 1990). At that time or shortly before or after, subsets of these progenitors or various combinations of their progeny begin to express additional marker genes, which has led to a detailed map of all heart cells (**Figure 3**): the segmentation homeobox gene *even-skipped* (*eve*) is expressed by two pericardial cells with large nuclei within each hemisegment (Frasch *et al.*, 1987); the homeobox gene *ladybird* (*lb*; Jagla *et al.*, 1997) and the COUP steroid receptor encoded by *seven-up* (*svp*; Mlodzik *et al.*, 1990) are expressed in two myocardial and two pericardial cells that do not overlap with the *eve* cells or with each other (see Han *et al.*, 2002); the T-box genes encoded by *dorsal cross* (*doc*) are also expressed in the *svp* myocardial cells (Reim *et al.*, 2003); the zinc finger gene *odd-skipped* (*odd*) is expressed in four pericardial cells, two of which overlap with the *svp* pericardial cells (Ward and Skeath, 2000); and *tinman* is expressed in four myocardial and at least four pericardial cells, two of which also express *lb* but not *svp* or *odd* (Alvarez *et al.*, 2003; Han and Bodmer, 2003). In the two anterior-most segments of the heart (T3/A1), all six myocardial cells express *tinman*, but not *svp*, and the pericardial cells are more numerous, many of which form the lymph gland, which becomes the larval blood forming organ (Rizki, 1978).

Additional markers of the myocardial cells are the ABC family gene *Dsur* (Nasonkin *et al.*, 1999; Lo and Frasch, 2001; T. Akasaka and R. Bodmer, unpublished data) and the T-box gene *neuromancer* (also known as H15; Griffin *et al.*, 2000; L. Qian and R. Bodmer, unpublished data). The basic helix–loop–helix motif encoding the *dHand* gene is expressed in all myocardial and pericardial cells (Moore *et al.*, 2000; Kolsch and Paululat, 2002). The myocardial cells share many of their muscle characteristics with other skeletal muscle cells, for example, expression of the muscle differentiation gene *Dmef2*; a MADS-box transcription factor (**Figure 1**; Lilly *et al.*, 1994; 1995; Nguyen *et al.*, 1994; Bour *et al.*, 1995), myosin heavy chain (Zhang and Bernstein, 2001), and beta-3-tubulin (Damm *et al.*, 1998).

Two sets of asymmetric cell division have been described in the cardiac mesoderm (**Figure 3**; Ward and Skeath, 2000; Alvarez *et al.*, 2003; Han and Bodmer, 2003): (1) the progenitors of the Svp lineage divide asymmetrically to generate Svp myocardial cells (SMC) and Svp-Odd pericardial cells (SOPC) (Ward and Skeath, 2000); (2) the progenitors of the mesodermal Eve lineage generate Eve pericardial cells (EPC) and muscle founders DA1 and DO2 (Park *et al.*, 1998; Halfon *et al.*, 2000; Carmena *et al.*, 2002; Han *et al.*, 2002; see **Chapter 2.1**). These asymmetric cell divisions are similar in the sense that they both distinguish between myogenic and nonmyogenic sibling cell fates. All other heart associated cell fates in the main portion of the heart (A2–8) appear to be generated by symmetric cell divisions, including the *tinman-lb* (TLMC) and the *tinman*-only (TMC) myocardial cells, the non-*svp* OPC, and the *tinman*-only pericardial cells (Alvarez *et al.*, 2003; Han and Bodmer, 2003). In T3/A1, all myocardial cells may have pericardial siblings but none express *svp*, and the exact lineage relations have yet to be determined.

2.6.2.1.3.2. Lineage tracing Three types of methods have been used to determine the lineages described above: (1) observation of cell division patterns (Carmena *et al.*, 1998, 2002; Halfon *et al.*, 2000); (2) clonal analysis using the site-specific Flp/FRT recombination system from yeast (Golic and Lindquist, 1989; Ward and Skeath, 2000; Alvarez *et al.*, 2003); and (3) analysis of cell cycle mutants to arrest early or late cell divisions during precursor lineages (Han and Bodmer, 2003). Flp/FRT

based clonal analysis is the most reliable method but also the most time-consuming when done at a sufficiently low clonal density. Clones have been generated at stage 8 (before mesodermal subdivisions) by heatshock induction of the yeast Flp recombinase in transgenic flies. This causes random recombination between two Flp recognition elements (FRTs), which results in excision of the region in between the FRTs and thus in reporter gene expression, such as *lacZ*, in the recombinant cell and all its progeny (Struhl and Basler, 1993). The patterns of co-labeled cells at low levels of induction then allow the determination of lineage relationships.

The asymmetric nature of the Eve lineages has first been suspected based on observation of the nuclear staining pattern of the Eve protein in the developing cardiac mesoderm (Carmena *et al.*, 1998), which was later confirmed by clonal analysis (Alvarez *et al.*, 2003). Two promuscular *eve* expressing clusters are specified in each half segment, out of which two progenitors emerge that undergo asymmetric cell divisions. In each segmental half, one Eve progenitor generates the two EPCs (Eve/Tinman positive) and a body wall muscle founder (DO2). The other Eve progenitor gives rise to a muscle founder (DA1) and an unidentified sibling. The final division of the immediate precursor of the EPCs is symmetrical. The *svp* expressing myocardial and pericardial cells are also generated again by an asymmetric lineage, as are the heart muscle cells in the anterior most myocardium (T3/A1). In contrast, the remaining myocardial and pericardial cells of the abdomen are apparently generated by symmetric lineages, each of which gives rise to two indistinguishable myocardial or pericardial progeny. In conclusion, all the lineages that participate in the embryonic heart have been elucidated (illustrated in **Figure 3**).

2.6.2.1.3.3. Cell cycle mutants Similar conclusions to those described in the previous section were reached by studying cell cycle mutants (Han and Bodmer, 2003). These mutants have been shown to arrest cell divisions at different stages and cell cycle number within the ectoderm. It is believed that most cells in the embryo undergo three partially synchronous rounds of cell division after blastoderm, in the mesoderm slightly earlier than in the ectoderm (Foe, 1989; Campos-Ortega and Hartenstein, 1997). The last round of global cell division, mitosis 16, is blocked in *cyclinA* (*cycA*) or *rca1* mutants (Knoblich and Lehner, 1993; Dong *et al.*, 1997), but *cyclinB* (*cycB*) mutants have no obvious effect. The *cycA* and *cycB* double mutants, however, act synergistically and arrest cell division at the G2/M transition of cycle 15 (Knoblich and Lehner, 1993). In embryos mutant for *string* (*stg*) (*cdc25* in yeast), cell division is arrested after blastoderm and does not enter metaphase of mitosis 14 (Foe, 1989; Edgar and O'Farrell, 1989, 1990). Additional genes are required for cells to exit the cell cycle, including the CDK inhibitor *dacapo* (*dap*) and *fizzy-related* (*fzr*), which negatively regulates cyclin levels. Loss of either gene causes cell division progression through an extra cycle, and overexpression inhibits mitosis and results in cell division arrest (Lane *et al.*, 1996; Sigrist and Lehner, 1997).

It is expected that the cell cycle has to be coordinated within the cardiac progenitors for correct specification of the progeny. A recent study shows that the heart precursors continue to differentiate in cell cycle mutants and in embryos in which cell cycle inhibitors are overexpressed (**Figure 4**; Han and Bodmer, 2003). As anticipated, the cell fate of symmetrically dividing progenitors of either myocardial- or pericardial-only lineages is not altered by premature arrest of cell division at cycle

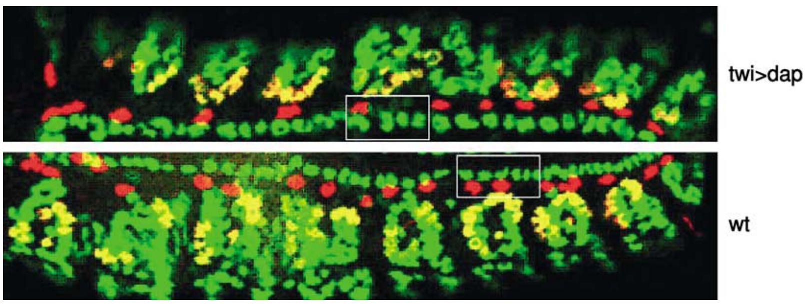

Figure 4 Premature cell cycle arrest changes the pattern of cardiac cell types revealing lineage relationships. Confocal images of the heart stained with antibodies against Dmef2 (green) and Eve (red). Bottom image shows the wild-type pattern of six myocardial cells (green) and two EPCs (red) and a double-labeled DA1 syncytial body wall muscle per half segment. Top image is an embryo in which the cell cycle inhibitor dacapo (dap) has been overexpressed in the mesoderm inhibiting the last division (cycle 16). As a consequence there is only one EPC and four myocardial cells per half segment (rectangle in top panel), instead of two and six, respectively (rectangle in bottom panel) (see text, **Figure 3**, and Han and Bodmer, 2003, for details). (Images kindly supplied by Zhe Han.)

16. By contrast, the progenitors of the asymmetric Eve and Svp lineages always adopt a myogenic, as opposed to the alternative pericardial, fate and are prevented from completing their last asymmetric divisions.

Interestingly, when cell division is halted earlier at cycle 15, as in *cycA*;*cycB* double mutants, only two of the normally six myocardial cells are formed in the A2–A7 segments: one expresses *tinman* and the other *svp*. This suggests that in each hemisegment two higher order myocardial progenitors are initially specified: one that divides twice symmetrically giving rise to the *tinman* expressing myocardial cells, whereas the other is likely to first divide symmetrically and then asymmetrically giving rise to the two *svp* myocardial and the two *svp* pericardial cells (**Figure 3**; Han and Bodmer, 2003). Taken together, there are probably 5–6 progenitors in each hemisegment that give rise to 14–16 heart associated cells (6 myocardial and 8–10 pericardial cells; see **Figure 3**).

2.6.2.1.3.4. Genetic control of asymmetric cardiac lineages As in the nervous system and other organs, a mechanism for generating cell type diversity within the heart field is by specifying alternative cell fates during asymmetric cell division. This involves intracellular determinants, which are localized asymmetrically in the predivisional cell, and which segregate to only one of the two daughter cells. In the nervous system of *Drosophila*, the membrane associated product of the gene *numb* has been shown to be necessary and sufficient for determining alternative daughter cell fates during asymmetric cell divisions (Uemura *et al*., 1989; Rhyu *et al*., 1994; Brewster and Bodmer, 1995; Spana *et al*., 1995; Guo *et al*., 1996; Spana and Doe, 1996; reviews: Vervoort *et al*., 1997; Lu *et al*., 1998; **Chapter 2.1**). In the daughter cell that inherits the Numb protein, the function of a transmembrane receptor protein encoded by *Notch* and a four-pass transmembrane protein encoded by *sanpodo* (*spdo*) is inhibited. As a consequence, the Numb-containing cell assumes a fate that is different from its sibling, in which Notch activity is unperturbed (Dye *et al*., 1998; Skeath and Doe, 1998; O'Connor-Giles and Skeath, 2003).

In the heart, the asymmetric *eve* and *svp* lineages are also under the control of *numb*, *Notch*, and *spdo* (Park *et al*., 1998; Ward and Skeath, 2000; Jagla *et al*., 2002; Alvarez *et al*., 2003; Han and Bodmer, 2003; **Chapter 2.1**). As in the nervous system, asymmetrically segregating Numb protein in the *eve* and *svp* lineages antagonizes *Notch* and *spdo* activity and causes distinction from the fate of its siblings. This mechanism is not limited to insect lineages since *numb* homologs have been identified also in vertebrates and shown to be localized asymmetrically during ventricular stem cell divisions in the developing brain (Verdi *et al*., 1996; Zhong *et al*., 1996, 1997). However, in vertebrates *numb* may function in maintaining the stem cell population of neural progenitors rather than participating in choosing specific pathways of differentiation (Petersen *et al*., 2002).

In contrast to the fly's asymmetric cardiac lineages, repression or constitutive activation of the *Notch* pathway has no apparent effect on the symmetric myocardial- or pericardial-only lineages (Han and Bodmer, 2003). For example, *numb* loss-of-function or ectopic activation of *Notch* results in twice the number of pericardial SOPC at the expense of the myocardial SMC, but the number of TMC is unaltered. Conversely, overexpression of *numb* causes the opposite phenotype in the *svp* lineage, again without affecting the TMC lineage. Thus, *Notch* signaling dramatically affects cell fate in asymmetric lineages by preventing a myogenic fate, but it is incapable of altering the myogenic fate of symmetrically dividing progenitors, even when its activated form is forcefully expressed in this lineage. Thus, inhibition of *Notch* activity is critical for specifying a myogenic cell fate only in asymmetric lineages; and a similar *Notch* responsive system is absent in symmetric lineages. Apparently, this switch from *Notch* insensitive to *Notch* responsive can occur from cell division to cell division, as in the case of the higher order *svp* progenitor, which first divides symmetrically then asymmetrically, or in the case of the EPC progenitor, which first divides asymmetrically and then symmetrically. It is conceivable that a common way to achieve increased cellular diversity in multicellular organisms is by switching to a *numb*/*Notch* responsive mode during evolution.

2.6.2.2. Genetics of Mesoderm Formation

2.6.2.2.1. *twist* and *heartless*: mesoderm and mesodermal movements As the formation of the heart depends on the prior formation of the mesoderm, mesoderm formation itself is directly linked to the determination of the dorsal–ventral axis of the embryo, and this has been studied in considerable detail. The dorsal–ventral axis depends on maternally active genes, which initiate the specification of this axis during oogenesis when the critical molecular coordinates are set up (review: St. Johnston and Nusslein-Volhard, 1992; **Chapter 1.2**). The executing morphogen of the dorsal–ventral axis is a Rel-related maternal transcription factor, encoded by

the gene *dorsal*, whose product accumulates in a ventrally increasing nuclear gradient at blastoderm stage prior to gastrulation. As a consequence of high levels of nuclear Dorsal protein, the first zygotic mesoderm-specific genes are activated in the ventral third of the blastoderm embryo: *twist*, which codes for a basic helix–loop–helix protein (Thisse *et al.*, 1988), and *snail*, which codes for a zinc finger protein (Boulay *et al.*, 1987). Both *twist* and *snail* are critical for specifying mesoderm, since in the absence of either gene function, the presumptive mesoderm does not form and gastrulation is blocked (Simpson, 1983; Nusslein-Volhard *et al.*, 1984; Alberga *et al.*, 1987; Thisse *et al.*, 1987). However, the ways in which they act are different: *twist* acts as a positive regulator of mesoderm-specific differentiation, while *snail*'s role in promoting mesoderm formation is by repressing neuroectodermal gene expression within the mesodermal anlagen (Kosman *et al.*, 1991; Leptin, 1991).

Before gastrulation starts, *twist* turns on a number of target genes throughout the mesodermal primordia of the trunk region which includes: *tinman*, a homeodomain containing nuclear protein (Bodmer *et al.*, 1990); *zfh1*, a nuclear protein containing a homeodomain and several zinc fingers (Lai *et al.*, 1991; Su *et al.*, 1999); *heartless* (as known as DFR1), a membrane protein of the FGF receptor family (Shishido *et al.*, 1993, 1997; Gisselbrecht *et al.*, 1996; Beiman *et al.*, 1996); *Drac1*, a GTPase (Luo *et al.*, 1994); *pointed P2*, an ETS transcription factor (Klambt, 1993); and *Dmef2*, the *Drosophila* homolog of the MEF2 family of MADS-box containing nuclear proteins (Nguyen *et al.*, 1994, Lilly *et al.*, 1994, 1995; Bour *et al.*, 1995). These early *twist* dependent transcription factors are candidates for executing the "mesodermal program," for example, by providing (transcriptional) context information for mesoderm-specific differentiation (see Section 2.6.4).

After gastrulation, the invaginated mesodermal mass flattens into a monolayer and spreads along the ectodermal body wall dorsally. Formation of this uniform cell layer closely apposed to the ectoderm is due to an active migratory process, which requires *heartless* function (Beiman *et al.*, 1996; Gisselbrecht *et al.*, 1996; Shishido *et al.*, 1997). In the corresponding mutants, the invaginated mesoderm barely flattens and for the most part is unable to reach the dorsal ectoderm; thus, heart and visceral muscle formation is severely reduced. As discussed below, secreted signals emanating from the dorsal ectoderm are crucial for inducing cardiogenic differentiation in the underlying mesoderm. Since these signals seem to act only over a short distance, they are unable to influence specification of the distant mesodermal mass in *heartless* mutants (see Bodmer and Frasch, 1999).

2.6.2.2.2. *tinman* and *dpp*: subdivision of the mesoderm Because the early Twist targets are expressed throughout the mesoderm, the patterning information that specifies the heart at the dorsal mesodermal margin must involve additional positional information. This information is provided by the ectoderm and is interpreted in a mesoderm specific fashion. In contrast to *heartless*' role in cell migration, the transcription factor Tinman is crucial for regionalization of the mesodermal monolayer, as a prerequisite of the development of (dorsal) mesoderm derived organs.

tinman is first expressed uniformly in the trunk presumptive mesoderm, and this expression is directly dependent on *twist*, the determinant of all mesoderm (Bodmer *et al.*, 1990; Yin *et al.*, 1997). After dorsal migration during gastrulation, *tinman* expression is limited to the dorsal portion of the mesoderm. In *tinman* mutants, derivatives of the dorsal mesoderm do not form, including the heart, the visceral, and many dorsal somatic body wall muscles (Azpiazu and Frasch, 1993; Bodmer, 1993). In contrast, a majority of ventral muscles and fat body form normally (for exceptions see Azpiazu and Frasch, 1993; Gorczyca *et al.*, 1994). Thus, specification of "dorsal mesoderm" is the first pivotal step in the process of mesodermal subdivision, prior to the specification of individual cell types or organs.

Before the mesoderm subdivides, *tinman* (and *Dmef2*) is restricted to the presumptive dorsal mesoderm (Bodmer *et al.*, 1990; Nguyen *et al.*, 1994). Since *tinman* mutants primarily affect dorsal mesoderm derived cell fates, it is likely that the dorsally restricted expression of *tinman* provides the key distinction between dorsal and ventral mesodermal cell fates, supported by the fact that absolutely no heart, visceral, and dorsal-most muscle progenitors are specified (Bodmer, 1993; Azpiazu and Frasch, 1993).

Since *tinman* is first expressed in all trunk mesoderm, it is unlikely to be the only determinant of dorsal mesoderm, and additional patterning mechanisms must operate to restrict its expression dorsally. Indeed, the dorsal ectoderm is closely apposed to the underlying mesoderm and, thus, is a likely source of this information, as is also suggested by the *heartless* phenotype of incomplete mesodermal migration (see above), and experiments in which gastrulation movements are blocked altogether (Baker and Schubiger, 1995). Earlier experiments in other insects have also put forward the proposition that heart formation depends on signals from

the overlaying ectoderm (Seidel *et al.*, 1940). In a set of elegant experiments, it was shown that the product of *decapentaplegic* (*dpp*), a secreted factor of the TGF-β superfamily and morphogen of the embryonic dorsal–ventral axis (Spencer *et al.*, 1982; Ferguson and Anderson, 1992; Francois *et al.*, 1994), acts as the key inductive signal, not only for dorsal ectodermal patterning, but also across germlayers for patterning the underlying dorsal mesoderm, which includes maintaining *tinman* expression (Staehling-Hampton *et al.*, 1994; Frasch, 1995). Like *tinman* mutants, embryos mutant for *dpp* lack all heart and visceral mesoderm formation, and *tinman* expression fades and does not become restricted to the dorsal mesoderm. Conversely, when the *dpp* pathway activity is expanded to more ventral regions, the *tinman* expression domain is also expanded ventrally (Frasch, 1995). Thus, *dpp* endows the dorsal mesoderm with the competence to form heart and other dorsal mesodermal cell types, in part via the direct regulation of *tinman* (Xu *et al.*, 1998; review: Bodmer and Frasch, 1999). *tinman* continues to be expressed in the visceral mesoderm for a short period of time as it segregates internally, and becomes prominently and exclusively expressed in cardiac progenitors of the embryonic trunk (**Figure 2a**). This heart-specific expression of *tinman* remains through adulthood (Molina and Cripps, 2001). Individual enhancer elements of the *tinman* gene have been identified that direct expression of the three early phases of *tinman* expression: the entire early mesoderm, the dorsal mesoderm, and cardiac mesoderm at the dorsal mesodermal edge (Yin *et al.*, 1997; Xu *et al.*, 1998, Venkatesh *et al.*, 2000).

2.6.2.3. Genetics of Heart Formation

Although the inductive *dpp* signal from the ectoderm apparently suffices to maintain *tinman* expression in the dorsal mesoderm and to specify the corresponding fates, the distinction of cardiac progenitors from other dorsal mesodermal derivatives and restriction of *tinman* expression to the cardiogenic region at the dorsal mesodermal edge requires further patterning information. Genetic evidence suggests that, within the context of the mesoderm the necessary and to some extent also sufficient cardiac patterning information is provided by the dynamic expression patterns of *dpp* and another secreted factor from the ectoderm, encoded by the secreted glycoprotein product of *wingless*, the original Wnt of *Drosophila*, which is expressed in segmental dorsal–ventral stripes oriented orthogonally to the broad anterior–posterior band of *dpp* (**Figure 5**; Lockwood and Bodmer, 2002). A model is presented in which the patterning information of these global positioning cues is interpreted mesoderm-specifically, and the crucial cardiogenic context for correct interpretation is given by Tinman, as well as by another transcription factor restricted within the mesoderm to the cardiogenic region, the zinc finger GATA factor encoded by the *pannier* gene (Lockwood *et al.*, 2001; Lockwood and Bodmer, 2002; Klinedinst and Bodmer, 2003).

2.6.2.3.1. Inductive factors: *wingless* and *dpp* Not only *dpp* but also *wingless* is absolutely necessary for cardiac mesoderm formation, but unlike *dpp*, *wingless* is not required for initiation of the visceral mesoderm (Wu *et al.*, 1995). Most, if not all, known components of the canocical *wingless* pathway participate in transducing the cardiogenic Wingless (Wg) signal (Park *et al.*, 1996). Interestingly, in vertebrates it is the noncanonical Wnt signaling that is required for promoting cardiogenesis (Pandur *et al.*, 2002). *wingless* is expressed until embryonic stage 10 in continuous, segmentally repeated ectodermal stripes, which later become interrupted in the lateral regions. The cardiac requirement parallels the *wingless* pattern of expression: it is required at stage 10 (Wu *et al.*, 1995), and again later at mid stage 11 (Jagla *et al.*, 1997). *dpp* also has two phases of expression: first in a broad dorsal ectodermal band until stage 9/10, then a brief period of no expression, and lastly by early stage 11 in a narrow band along the dorsal edge, immediately above the cardiac progenitors, as well as in a band along the ventrolateral region. A specific requirement for the late pattern of *dpp* expression has not yet been demonstrated rigorously, because, unlike in the case for *wingless*, there are no steeply temperature-sensitive mutants available for *dpp*. Interestingly, *tinman* expression, beginning with the restriction to dorsal mesoderm, closely follows the *dpp* pattern in the ectoderm. In contrast, *wingless* expression parallels *tinman* expression much less, but does overlap with it (**Figure 5**).

Given that *wingless* and *dpp* are expressed in dynamic patterns, and are used manifold during development for partitioning the embryo and for specifying tissues, the question arises how is their patterning information computed in order to provide the precision of spatial positioning of the cardiac precursors within the embryo? This led to the hypothesis that it is the convergence of both *wingless*- and *dpp*-dependent signals that is necessary to maintain *tinman* expression in the cardiac progenitors and to specify cardiac-specific cell fates, and that the correct cardiogenic interpretation of

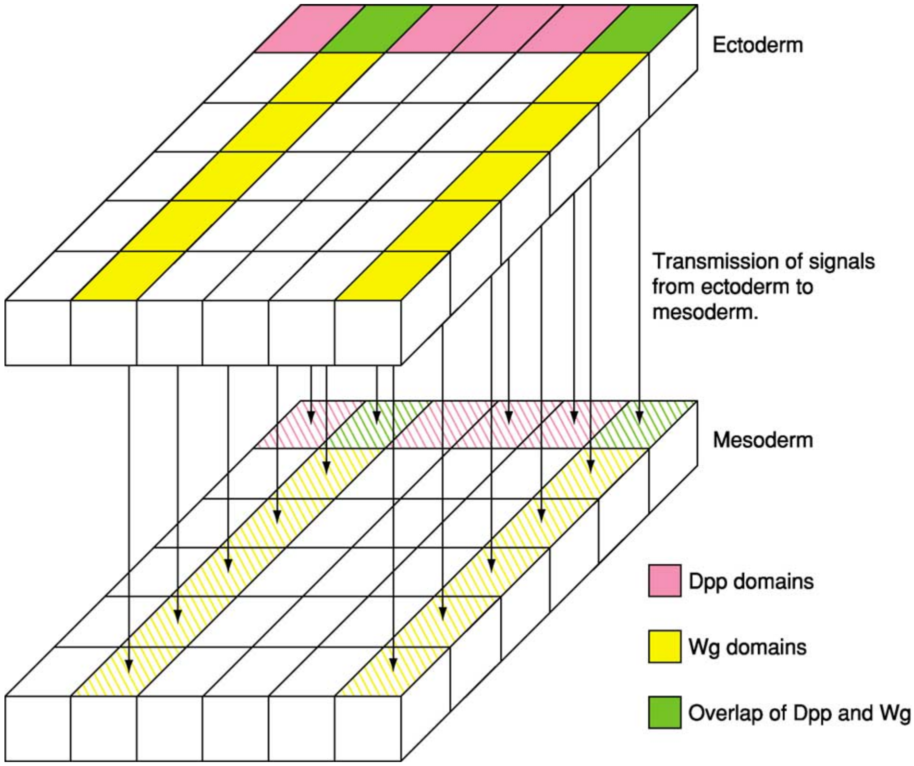

Figure 5 Diagrammatic representation of the convergence of the secreted signals Dpp and Wg from the ectoderm on the cardiogenic region in the underlying mesoderm. (Diagram kindly supplied by Wendy K. Lockwood.)

this convergence is provided by the presence of *tinman* in the dorsal mesoderm (Lockwood *et al.*, 2001; Lockwood and Bodmer, 2002). Thus, the heart is specified by *tinman*-expressing mesodermal cells in dorsal segmented clusters, where these cells are also exposed to signaling by *wingless* and *dpp*, both at early (stage 9/10), as well as later (stage 11) stages (**Figure 5**).

To test this hypothesis, *wingless* and/or *dpp* were misregulated by uniform overexpression in the mesoderm, with the expectation that wherever this misregulation resulted in an early and late coincidence of all three factors (Tinman, Wingless, and Dpp), cardiac specific differentiation would be initiated. For example, uniform *wingless* does not cause ectopic heart formation since no persistent trifold coincidence is generated. In contrast, uniform *dpp* does generate heart progenitors ventrally, since *tinman* is also expanded ventrally by ectopic *dpp* (see Frasch, 1995), and the late *wingless* is present in a dorsal as well as ventral stripe. Thus, the trifold dorsal and ventral overlap induces a ventral in addition to a dorsal heart (see Lockwood and Bodmer, 2002, for details).

2.6.2.3.2. Transcription factors: *tinman* and *pannier* The information content of the Wingless and Dpp morphogens alone, however, cannot account for the tissue specificity of cardiac differentiation, since they overlap often within the embryo causing a variety of outputs. Indeed, the pattern of *tinman* expression is also dynamic, first in all trunk mesoderm, then in dorsal mesoderm and finally along the dorsal mesodermal edge coincident with the cardiac progenitors, the latter pattern being dependent on both morphogens. It is possible that Wingless and Dpp are merely required to position and maintain *tinman* appropriately, and it is *tinman* that then acts autonomously in initiating cardiogenesis. If this were the case, one would expect that simply overexpressing *tinman* at the time when the heart progenitors are specified would be sufficient to create ectopic heart induction. However, uniform expression of *tinman* does not cause ectopic cardiogenesis beyond the dorsal edge of the mesoderm (Lockwood and Bodmer, 2002).

If the trifold overlap of *wingless*, *dpp*, and *tinman* is indeed instructive in initiating cardiogenesis, then it may be possible to generate cardiac fates ectopically, for example, at nonmesodermal intersects of *wingless* and *dpp*. Indeed, overexpression of *tinman* in the embryonic imaginal disc primordia, an obligatory ectodermal intersection of *wingless* and *dpp*, results in induction of cardiac specific markers

(Lockwood and Bodmer, 2002). Therefore, *wingless* and *dpp* are not only required to correctly position cardiogenic context information, such as *tinman*, within the mesoderm, but their signaling activities are directly participating in heart specification.

The necessary and sufficient roles of these three factors provide a minimal genetic framework for cardiac induction. The next question is how ectodermal Wingless and Dpp transmit their signal to the underlying mesoderm? Are the signaling pathways acting directly on the relevant enhancers of *tinman* and other genes expressed early in the heart or are there intermediates? Interestingly, the enhancer responsible for Eve expression in a subset of cardiac progenitors directly depends on the Wingless and *dpp* signaling pathways (Halfon *et al*., 2000; Knirr and Frasch, 2001; Han *et al*., 2002). In contrast, the cardiac specific enhancer of *tinman* (Venkatesh *et al*., 2000) may not be directly regulated by Wingless, but rather depend on the intermediary Forkhead transcription factor encoded by *sloppy paired* (*slp*), which is directly induced by the *wingless* pathway in corresponding stripes within the mesoderm (Lee and Frasch, 2000).

Another question is how the *dpp* signal is converted into cardiac specific gene activation. Addressing this question is complicated by the fact that *dpp* is the principal zygotic organizer of dorsal–ventral patterning and because of its role in dorsal closure of the embryo, which indirectly affects cardiac morphogenesis. One of the ectodermal targets of the Dpp morphogen is the GATA factor Pannier (Ramain *et al*., 1993; Winick *et al*., 1993; Ashe *et al*., 2000; Herranz and Morata, 2001), which is also expressed in the heart forming region of the mesoderm at the time when *tinman* is restricted to the cardiac primordia (mid to late stage 11; Gajewski *et al*., 1999; Klinedinst and Bodmer, 2003). This raises the possibility that Pannier may be a mediator of the ectodermal Dpp signal within the mesoderm to correctly specify and position the heart to the dorsal mesodermal margin.

In *pannier* mutants, formation of the *tinman* expressing cardiac mesoderm at mid stage 11 is severely reduced (Klinedinst and Bodmer, 2003). To determine the tissue specific requirement of *pannier*, two complementary sets of experiments were carried out: (1) a dominant-negative construct containing the N-terminal zinc fingers fused to the Engrailed repressor domain was expressed in the mesoderm or the ectoderm; and (2) in rescue experiments *pannier* cDNA was expressed in either germlayer of *pannier* mutants. It was found that *pannier* is primarily required within the mesoderm for heart formation, suggesting that this gene indeed participates in specifying the heart forming region alongside *tinman* (Klinedinst and Bodmer, 2003). Interestingly, however, ectodermal *pannier* is also needed for heart formation, at least in part by maintaining *dpp* expression after stage 11/12. It is not yet known if *pannier* is activated directly by the *dpp* pathway, as *slp* is by the *wingless* pathway (Lee and Frasch, 2000), or indirectly via another mediator.

Not all the heart lineages are equally affected in *pannier* mutants. For example, the *ladybird early* (*lbe*) and *svp* lineages are more severely reduced than the *eve* lineage, suggesting that *pannier* may also take a direct part in the specification of certain lineages. In agreement with this idea, GATA consensus sites were found in the cardiac enhancer of *tinman* but not in the mesodermal *eve* enhancer (Han *et al*., 2002; J. Liu and R. Bodmer, unpublished data). *pannier* is also a likely direct target of Tinman (Gajewski *et al*., 2001), suggesting that both of these transcription factors participate in maintaining each others expression. One can envision the following sequence of events during cardiogenesis: at stage 9/10 Dpp maintains *tinman* expression in the dorsal mesoderm and *pannier* expression in the dorsal ectoderm (Xu *et al*., 1998; Ashe *et al*., 2000). At early to mid stage 11, Tinman and Dpp/Wingless initiate Pannier in the cardiogenic region, and Pannier and Dpp/Wingless maintain Tinman expression in the heart field. Later, Tinman and Pannier maintain each other, and ectodermal Pannier maintains late Dpp expression. In conclusion, Pannier may have a pivotal role in cardiac specification as Tinman has. Another target of Dpp, the *dorsal cross* (*doc*) genes encoding T-box transcription factors, are required for repressing *wingless* in the lateral ectoderm (Reim *et al*., 2003), thus likely contributing to the dorsal restriction of *tinman* and *pannier*. Interestingly, the dorsally restricted strips of *wingless* expression at stage 11 depend on *pannier* as well (S.L. Klinedinst and R. Bodmer, unpublished data). Thus, the two Dpp targets, *doc* and *pannier*, contribute in different ways, both directly and indirectly, to the specification and positioning of the heart.

Overexpression experiments suggest that *tinman* and *pannier* may act synergistically, or in parallel, in specifying cardiac development (Klinedinst and Bodmer, 2003): forced expression of *tinman* has little capacity in promoting ectopic heart formation, and pan-mesodermal *pannier* only transiently induces *tinman* in ventrolateral regions. However, when both are expressed throughout the mesoderm simultaneously, a robust and sustained initiation of cardiac marker genes occurs, for example, of the basic helix–loop–helix transcription factor encoded

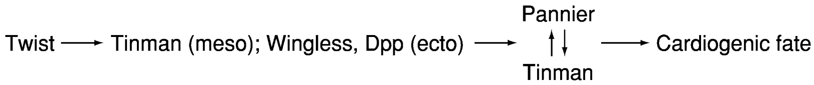

Figure 6 Genetic cascade of heart specification.

by *dHand* and of the ABC-class transmembrane protein encoded by *Dsur* (Klinedinst and Bodmer, 2003). This is consistent with *in vitro* experiments using vertebrate cell lines, in which it was shown that the vertebrate homologs of these genes activate target genes synergistically (e.g., Sepulveda *et al.*, 1998, 2002; Lee *et al.*, 1998). In conclusion, it may be that once *tinman* and *pannier* are activated in the prospective heart region, they may no longer require the parallel function of *wingless* and *dpp*, but now may function autonomously, analogous to homeotic selector genes, in specifying a cardiac fate (**Figure 6**).

There is a third transcription factor that is confined to the cardiac mesoderm at late stage 11, the time of heart progenitor formation: the tandem T-box factors encoded by *neuromancer I* (also known as *H15*; Griffin *et al.*, 2000) and its neighbor *neuromancer II* (L. Qian and R. Bodmer, unpublished data). Not only is this gene pair expressed at the right time in the right place, but also deletion mutants dramatically reduce heart progenitor formation and mesodermal overexpression transiently induces ectopic *tinman* expression, reminiscent of *pannier*, thus consistent with a central role in cardiac specification (L. Qian and R. Bodmer, unpublished data). Moreover, *in vitro* protein binding and transactivation studies in vertebrates also suggest a synergistic relationship between these three transcription factors (Garg *et al.*, 2003; Stennard *et al.*, 2003). Thus, it will be interesting to see if the combination of *tinman*, *pannier*, and *neuromancer* is not only necessary but also sufficient in promoting cardiogenesis.

2.6.2.4. Genetics of Cardiac Cell-Type Specification

2.6.2.4.1. *even-skipped* and *ladybird* Although more work is required to understand the details of cardiac initiation, the principal components of the genetic framework that generates cardiac competence along the dorsal mesodermal margin are now identified: inductive patterning information provided by *wingless* and *dpp*, and mesodermal context information provided and integrated by *tinman* and *pannier* (and perhaps *neuromancer*). The next question that needs to be addressed is how individual cell fates are specified within discrete locations along the heart primordium. It is important to

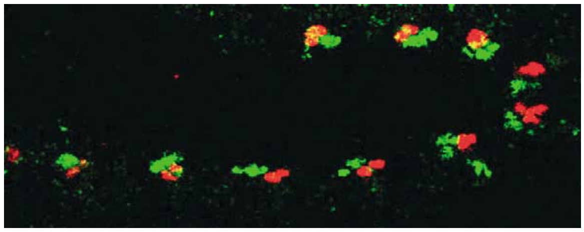

Figure 7 Side view of a late-stage 11/12 embryo double-labeled for Eve (red) and Lbe (green) protein in cell clusters within the cardiac mesoderm (compare with **Figure 2a**). Anterior is to the left. (Confocal image kindly supplied by Jiandong Liu.)

keep in mind that the specification of distinct cell types may occur concurrently or in parallel with the overall determination of "cardiac mesoderm." Between early stage 11 and stage 12, at least four groups of heart progenitors emerge within the prospective cardiogenic region as segmental clusters arranged in a stereotyped positional and temporal order, expressing either *eve*, *lbe*, *svp*, or *odd* (Frasch *et al.*, 1987; Jagla *et al.*, 1997, 2002; Ward and Skeath, 2000; Han *et al.*, 2002).

The first clusters to emerge within a segmental unit are the *eve* cells at stage 10/early stage 11 immediately underneath the ectodermal *wingless* stripes. This is at the time when *tinman* is still expressed in the broad dorsal mesoderm domain. This expression is before *pannier* and *tinman* are activated in the cardiogenic mesoderm at mid stage 11. Consistent with this is the finding that *tinman* is absolutely required for initiating mesodermal *eve* expression, whereas in *pannier* mutants the *eve* clusters are only moderately affected, unlike the other later-emerging clusters (Klinedinst and Bodmer, 2003). The specification of the cell types expressing mesodermal *eve* and the regulation of this expression has been extensively studied (see also next section: Carmena *et al.*, 1998; Buff *et al.*, 1998; Su *et al.*, 1999; Halfon *et al.*, 2000; Carmena *et al.*, 2002; Han *et al.*, 2002; Bidet *et al.*, 2003). The two *eve* progenitor cells in each hemisegment (**Figure 7**) appear to be selected from larger "promuscular clusters" by *Notch*-dependent lateral inhibition. These promuscular clusters, in addition to requiring *dpp* and *wingless* signaling, also require *ras*-mediated input from EGF and FGF receptor tyrosine kinases. Moreover, after the progenitors have divided, correct differentiation of pericardial EPCs requires an additional layer of context information, encoded by the early pan-mesodermal

gene *zfh-1*, which at this stage is expressed in all pericardial cells (Lai *et al*., 1991; Su *et al*., 1999).

Eve is not only a marker for the heart-associated cells it is expressed in, but is also required autonomously within these cell for their differentiation (Su *et al*., 1999; Han *et al*., 2002; Jagla *et al*., 2002; M. Fujioka, R.J. Wessells, Z. Han, R. Bodmer, and J.B. Jaynes, unpublished data). To separate the role of *eve* during segmentation from its role in the mesoderm, the enhancer responsible for mesodermal *eve* expression (see below) was selectively eliminated in a genomic rescue construct (Fujioka *et al*., 1999). Flies that are null mutant for *eve* but contain this "*eve* meso minus" rescue construct as a transgene are viable and fertile, and most cardiac cell types and the linear heart tube appear to form normally, except they lack all progeny of the mesodermal *eve* progenitors, the EPCs, and the DA1/DO2 muscles. Interestingly, these flies exhibit dramatically compromised heart function and lifespan, suggesting for the first time a specific role for at least one set of pericardial cells in insects (M. Fujioka, R.J. Wessells, Z. Han, R. Bodmer, and J.B. Jaynes, unpublished data).

Immediately anterior to the *eve* clusters emerge the *lbe* expressing progenitors at late stage 11 (**Figure 7**; Jagla *et al*., 1997). In deficiency embryos that delete the two tandem *ladybird* genes (*lbe* and *ladybird late*, *lbl)* the *eve* clusters are enlarged anteriorly; and mesodermal overexpression of *lbe* suppresses *eve* (Han *et al*., 2002; Jagla *et al*., 2002;). Conversely, "*eve* meso minus" rescue embryos have expanded *lbe* expression; and mesodermal overexpression of *eve* eliminates *lbe* in the cardiogenic region. Therefore, the distinction of the *eve* versus *lbe* clusters is maintained by a cross-repressive relationship between these two genes in the cardiogenic region. As discussed below, Lbe directly represses *eve* transcription in the cells anteriorly to the *eve* clusters (Han *et al*., 2002).

The anterior-most myocardial cells expressing *lbe* at the tip of the heart, the outflow track, are contacted by a group of ectodermal *lbe*-expressing cells, the heart-anchoring cells (HANCs; Zikova *et al*., 2003). The function of *lbe* apparently is necessary for this contact and for outflow track morphogenesis. Interestingly, when *lbe* expression is blocked only in the myocardial cells by ectopic *eve* expression in all mesoderm or specifically in the *tinman* expressing myocardial cells, the stereotyped morphological arrangement of the cardiac outflow region is also disrupted (Zikova *et al*., 2003). These findings suggest that the role of the HANC cells in fly heart morphogenesis is reminiscent of the role the neural crest plays in vertebrates, which is also in patterning the cardiac outflow track (Kelly and Buckingham, 2002).

The *svp* expressing cell clusters arise at late stage 11/12 near the segmental boundaries. *svp* is first coexpressed with *tinman*, but then suppresses it in the *svp* cells (Gajewski *et al*., 2000; Molina and Cripps, 2001; Lo and Frasch, 2001). Unlike *lbe* and *eve*, however, gain- or loss-of-*svp*-function does not influence cardiac *eve* or *lbe* expression. Later in embryogenesis, *wingless* is expressed in the ostia forming *svp* myocardial cells of the posterior heart segments A6–A8. In *svp* mutants, *wingless* is no longer expressed in the heart and the function of the ostia as inlet valves for the hemolymph into the heart seems to be compromised (Lo *et al*., 2002; Ponzielli *et al*., 2002).

There are two sets of *odd* expressing cells within the forming heart (Ward and Skeath, 2000): one co-expresses *svp* (see above) and the other will give rise to a set of pericardial-only cells. The function of *odd* in the heart has not yet been determined. There are probably additional *tinman*-expressing cells within the heart-forming region that are not yet accounted for by specific marker gene expression, such as two *tinman*-only myocardial cells (also expressing the muscle-specific marker *Dmef2*) and two *tinman*-only pericardial cells (also expressing the pan-pericardial marker *zfh1*) in each half segment.

2.6.2.4.2. Combinatorial transcriptional control: the *eve* mesodermal enhancer How is the information that specifies a certain population of (cardiac) cells integrated at the transcriptional level that allows the precise spatial positioning of the corresponding cell types within the embryo? For example, how is the highly stereotyped and restricted pattern of *eve* expression in the mesoderm along the dorsal edge of the mesoderm achieved? The identification of an enhancer element that is necessary and sufficient for faithful expression confined to the mesodermal *eve* clusters has provided a model to answer these questions (Fujioka *et al*., 1999; Halfon *et al*., 2000; Knirr and Frasch, 2001; Han *et al*., 2002). Studying this enhancer not only provided insight into how the positional information that specifies the location of the heart within the mesoderm is integrated transcriptionally, but also how subpatterns of gene expression are achieved within the heart field (Han *et al*., 2002). First, how *eve* is activated within the cardiac mesoderm, and then how it is confined to a small subset of heart progenitors is described.

Within a few hundred base pairs of genomic region 6 kb 3′ to the *eve* coding region, multiple consensus or *in vitro* binding sites have been

identified for all the transcription factors that have been shown to be required genetically for *eve* expression in the heart forming region. Among them are sites for Pangolin/dTCF (*wingless* pathway), Mad (*dpp* pathway), Pointed (ETS factor, *ras* pathway), Twist, and Tinman (Halfon *et al*., 2000; Knirr and Frasch, 2001; Han *et al*., 2002). The consensus appears to be that there are multiple sites for each transcription factor, which act overall in an additive fashion within and in between classes of sites. For example, mutation of progressively more Tinman sites eventually eliminates enhancer-driven reporter gene expression in transgenic flies. Similarly, mutation of only a few sites of two different classes, each set alone not having much influence on expression, also eliminates expression. Thus, the basic combinatorial genetic network that is in control of positioning cardiogenic competence to the dorsal edge of the mesoderm also acts combinatorially at a single enhancer. Of note, however, is the finding that a crucial cardiac determinant, *pannier*, apparently only acts indirectly here, via *tinman* most likely, since this enhancer apparently lacks GATA consensus binding sites and mesodermal *eve* expression is less affected in *pannier* mutants than cardiac *tinman* is (Klinedinst and Bodmer, 2003; Z. Han, M. Liu, and R. Bodmer, unpublished data). Moreover, mesodermal *eve* apparently is directly regulated by the *wingless* pathway, even though cardiac restricted *tinman* may not be. Thus, there are important differences in the details of how each gene's expression in the cardiogenic region is regulated.

Although the above activator inputs explain well why mesodermal *eve* is expressed within the heart field of the embryo, they are not sufficient to elucidate how *eve* transcription is confined to a rather small cluster of heart associated cells within each half segment (**Figure** 7). Since *lbe* acts genetically as a repressor of *eve*, it may do so by direct interaction with the mesodermal *eve* enhancer. Indeed, Lbe protein binds to the enhancer *in vitro* and mutating the corresponding sites in the enhancer leads to a dramatic expansion of reporter gene expression to fill the entire cardiogenic region (Han *et al*., 2002). Moreover, overexpression of *lbe* is no longer able to suppress the cardiac-wide reporter gene expression driven by this mutant enhancer, thus further supporting a direct regulation by Lbe. While Lbe represses *eve* anteriorly, it remains to be elucidated how *eve* is restricted posteriorly (see **Figure** 7). Whatever the outcome, the mechanism of regulation must include the same sites that Lbe binds to.

Studying gene regulation by taking enhancer regions out of the normal gene context and examining their ability to drive reporter gene expression in a spatially and temporally restricted fashion in the developing embryo has much enhanced our understanding of the mechanisms involved. To validate the findings, however, it has not been practical to manipulate enhancers within the context of the endogenous gene. An exception is the case of the mesodermal *eve* enhancer: the lack of *eve* cluster formation in "meso minus" *eve* rescue flies (see Section 2.6.2.4.1) demonstrates that this enhancer is not only sufficient to drive mesodermal *eve* expression faithfully, but despite its location far downstream of the coding region, it is absolutely required within the context of the entire *eve* gene (Fujioka *et al*., 1999; Han *et al*., 2002). Interestingly, mesodermal *eve* expression is also abolished when only a portion of the enhancer is deleted in the rescue construct, leaving intact an adjacent region, which is sufficient to drive expression faithfully when assayed in isolation. Thus, within the context of the entire gene, the regulatory requirements may be more complex and stringent than is apparent from studying isolated enhancers.

2.6.2.4.3. *pointed*, *msh*, and *hedgehog* Although a basic genetic framework is now available of how the heart is positioned within the mesoderm and how individual cell fates are generated, additional gene functions are likely to be involved in fine-tuning the spatial precision or exact number and relative position of individual cardiac progenitors. Two new gene functions have recently been identified that when mutated cause a dramatic increase in the myocardial cell population of the heart: the ETS gene *pointed* and the *muscle-specific homeobox* (*msh*) gene (Jagla *et al*., 2002; Alvarez *et al*., 2003). It is likely that in mutants of these genes, more heart progenitors are recruited from the dorsal mesoderm, perhaps at the expense of dorsal skeletal muscles.

In *pointed-P2* isoform mutants, it is primarily the *svp* myocardial cells that are increased in number at the probable expense of skeletal muscles and/or pericardial-only progenitors (Alvarez *et al*., 2003). Conversely, pan-mesodermal *pointed-P2* expression can rescue *pointed* null mutants, but does not diminish the normal complement of myocardial cells, suggesting that by itself *pointed-P2* is a permissive cue to restrict myocardial progenitors to the normal number. As suggested by Alvarez *et al*. (2003), this function of *pointed-P2* in determining myocardial cell number may be in addition to its function as an effector of the *ras* pathway, and thus independent of EGF or FGF signaling.

In the case of *msh* mutants, a set of dorsal skeletal muscle precursors, which normally express *msh*,

seem to be redirected towards a myocardial fate, reminiscent of *pointed* mutants (Jagla *et al*., 2002). In contrast to the *pointed* phenotype, however, loss-of-*msh* may also increase rather than decrease the pericardial cell number, suggesting that *msh* and *pointed*'s cardiogenic function differ to some extent. Because *Dmef2*-positive myocardial cells and *odd*-positive myocardial cells are increased in number in *msh* mutants, it might be that this is largely due to an increase in the *svp* expressing progenitors (see lineage in **Figure 3**), although the *tinman*-positive myocardial cells are also increased. In contrast to *pointed-P2*, overexpression of *msh* diminishes myocardial and pericardial cell numbers, affecting *lbe* expression more severely than *eve*. It has been proposed that *lbe*, *eve*, and *msh* are opposing each other's expression and function in a cross-regulatory network to specify spatially restricted cardiac (and skeletal) cell fates (Jagla *et al*., 2002).

A question that has not yet been resolved is how individual cell clusters are positioned relative to one another within the cardiogenic region. Even though both the *eve* and the *lbe* clusters require *dpp*, *wingless*, *tinman*, and *pannier* expression, and repress each other, why is *eve* always posterior to *lbe* within each segmental unit (**Figure 7**)? Clearly, additional patterning information must come into play. One such source may be the striped expression of *hedgehog*, which is just posterior to the *wingless* stripes and required for maintaining its expression. Consequently, *hedgehog* is also required for heart formation altogether, as is *wingless* (Wu *et al*., 1995; Park *et al*., 1996). In a genetic situation in which *hedgehog* is eliminated but *wingless* is maintained ectopically by forced expression in the mesoderm or in the normal *wingless* domain, no *eve* cell clusters form and the *lbe* clusters are expanded within the cardiogenic region (J. Liu, L. Qian, and R. Bodmer, unpublished data). The converse phenotype of expanded *eve* and reduced *lbe* clusters is observed when *hedgehog* is overexpressed, which is reminiscent of *ras* pathway activation (Buff *et al*., 1998; J. Liu, L. Qian, and R. Bodmer, unpublished data). Indeed, manipulation of *hedgehog* alters the expression level of *rhomboid* in the dorsal mesoderm, a protease that regulates EGF receptor-mediated *ras* activation. Taken together, these findings suggest that striped *hedgehog* signaling positions mesodermal *eve* expression nearby in the underlying mesoderm, via augmenting *ras* signaling. Further away from the *hedgehog* stripes then emerge *lbe* clusters, which do not require *hedgehog*. The mutual repression between *eve* and *lbe* then maintains the stereotyped anterior–posterior arrangement of these cell fates within each segment. In conclusion, some of the basic genetic principles by which individual heart progenitors and their progeny are specified, positioned, and distinguished from their neighbors are now understood.

2.6.2.5. Homeotic Control in Anterior–Posterior Regionalization of the Heart

Although before the formation of the heart tube, the anterior portion of the heart (A2–A5), the aorta, appears to be indistinguishable from the posterior portion (A6–A8) (**Figure 2**), at later stages the posterior heart is wider (**Figures 1 and 3**), contains the main pacemaker activity (see Section 2.6.3), and the *svp* myocardial cells express *wingless* and differentiate as ostia, the hemolymph inlet valves (Molina and Cripps, 2001). Several recent studies have elucidated the genetic control of this broad regional distinction between anterior and posterior heart by the *hox* genes of the Bithorax Complex (Lo *et al*., 2002; Lovato *et al*., 2002; Ponzielli *et al*., 2002; review: Lo and Frasch, 2003; **Chapter 1.8**). Of these genes, *abdominal-A* (*abd-A*) seems to be the principal player that discriminates between the aorta and the posterior heart by acting as the homeotic selector gene of the posterior heart fate.

The pattern of *hox* expression in the forming heart is arranged in a sequential anterior–posterior pattern, similar to their cuticular patterning role in the overlaying ectoderm (see **Chapter 1.8**), although the segmental register seems to be shifted posteriorly by 2–4 segments. In the anterior aorta (T3–A1), *Antennapedia* (*Antp*) is expressed primarily in the A1 region. No other *hox* gene is known to be expressed in the anterior-most region of the heart outflow track (T3). *Utrabithorax* (*Ubx*) is expressed at high levels in the posterior aorta (A2–A5) and at lower levels more posteriorly. *abd-A* expression is confined to the heart proper (A6–A8). In the posterior-most four myocardial cells (in A8) *Abdominal-B* (*Abd-B*) is highly expressed. In order to determine the *hox* gene function in cardiac specification, three markers were used in addition to morphological criteria: *troponinC-akin1* (*tina1*) is expressed at high levels in posterior heart and not in the aorta (Lovato *et al*., 2002), while *wingless* and a truncated heart enhancer of *tinman* are expressed in the ostia-forming *svp* myocardial cells of the heart (Lo *et al*., 2002).

In null mutants of *abd-A*, the posterior heart markers *tina1* and *wingless* are no longer expressed and the morphology of the posterior heart is narrower like that of the aorta. Moreover, *Ubx* is now expressed at higher levels in the posterior heart. Conversely, in embryos in which *abd-A* is expressed uniformly in the mesoderm, the anterior portion of

the heart (T3–A5) is now wider in diameter expressing *tina1* as does the posterior heart, *Ubx* expression is reduced, and in each segment double pairs of *svp*- and *wingless*-expressing myocardial cells form an apparently functional ostia. Interestingly, even the outflow track segments (T3–A1), which normally derive from lineages that are distinct from those in posterior segments (Alvarez *et al*., 2003; Han and Bodmer, 2003), are transformed towards the posterior heart identity. When a weaker, later onset but heart-specific driver is used, a similar phenotype is observed in the region of the posterior aorta but not of the outflow track, suggesting that the posterior aorta is either more susceptible to *abd-A* or for a longer time period than the anterior-most segments. A temporal difference in outflow track versus aorta specification is consistent with the finding that the last divisions of the outflow track lineages takes place before those of the more posterior segments (Han and Bodmer, 2003). It will be interesting to see if an anterior *hox* gene, such as *Antp*, participates in endowing the outflow track primordium with its distinct progenitor lineages. Taken together, these findings suggest that the *hox* genes, at least in the case of *abdA*, function autonomously within the heart progenitors to promote correct regional identities of differentiation.

Since *abd-A* is expressed and required in the posterior heart, *Ubx* may have a similar role as a homeotic selector gene in specifying a "posterior aorta" fate, as would be expected according to the "posterior prevalence" model of *hox* gene function, in which the anterior expression domain is functionally most important. Indeed, loss-of-*Ubx*-function does not alter posterior heart differentiation, and *abd-A* is slightly elevated in the aorta. However, the aorta of *Ubx* mutants does not undergo a dramatic change in its developmental program of the myocardial cell specification, except for some abnormalities in epithelial polarity (Ponzielli *et al*., 2002), since *tina1* and *svp* appear to be expressed normally. No significant additional changes are observed in the aorta of *Ubx,abd-A* double mutants, but insufficient landmarks have been monitored to decide upon a possible transformation towards an outflow track fate. In contrast to the heart tube itself, however, the primordia of the larval blood-forming organs, the lymph glands (**Figure 3**), which are pericardial specializations in the A1 region of the heart, are expanded along the entire posterior aorta in *Ubx* mutants (Mastick *et al*., 1995).

Embryos with pan-mesodermal overexpression of *Ubx* have defects in ostia formation of the posterior heart and in overall morphology, but *abd-A* is expressed normally. Unexpectedly, this gain-of-*Ubx*-function situation results in anterior expansion of the posterior heart marker *tina1* throughout the aorta, and an additional pair of ostia develops in the posterior-most segment of the aorta (A5). This is reminiscent of the *abd-A* overexpression phenotype (see above), suggesting that in this over expression assay, *Ubx* can partially substitute for its relative *abd-A*. In contrast, *abd-A*'s posterior relative *Abd-B*, which is only present in a few posterior-most myocardial cells after the heart tube has formed, completely suppresses cardiogenesis when overexpressed throughout the mesoderm. Conversely, in *Abd-B* mutants, additional heart progenitors develop more posteriorly, resulting in a "longer" heart (Lo *et al*., 2002). Thus, *abd-A* and possibly other *hox* genes act as positive regulators, whereas *Abd-B* acts as a negative regulator of heart development.

2.6.3. Heart Function

2.6.3.1. The Cardiac Pacemaker

The regular, rhythmic beat of the heart is generated by a membrane-bound oscillator consisting of an ensemble of ion channels. This is true whether the oscillation arises in a nerve ganglion (neurogenic) or the muscle (myogenic) of the heart itself. The horseshoe crab, *Limulus*, has for a long time been the type specimen for the neurogenic heart, and it was assumed that the majority of arthropods possessed a similar mechanism (Prosser and Brown, 1961). This conclusion for insects was largely based on research done on the cockroach heart, which is heavily innervated and seemed initially to be neurogenic (Miller, 1985). Nonetheless, all insect hearts thus far investigated, including that of the cockroach, have cardiac pacemakers integral to the myocardium, although extensive control by neural systems is widespread (Miller, 1985).

2.6.3.1.1. Vertebrate hearts Vertebrate myogenic cardiac pacemakers have been intensely studied over a long period of time. Given the observed conservation of ion channel-based systems across phyla (Hille, 2001), it is reasonable to start with vertebrate pacemakers as models, giving a solid basis from which to consider insect and, in particular, *Drosophila* pacemaking mechanisms. The underlying biophysics of the oscillatory behavior may vary in detail, but the overall similarities are striking and insect research has already carried over into understanding vertebrate mechanisms, with implications for human health.

In the lowest vertebrates, initiation of heartbeat starts in the weakly muscled *sinus venosus* (SV),

which receives the systemic blood (Torrey and Feduccia, 1979; Kardong, 2002). Tissue from all chambers of the heart retain a spontaneous beat upon dissection, but the SV, as the first chamber through which blood must pass, has a beat that is measurably faster than those downstream (review: Patten, 1949). In the intact heart, the beat from this chamber triggers a peristalsis-like wave of contractions that passes from chamber to chamber, thus entraining or driving the oscillations in the other, slower-beating, chambers (Adolph, 1967). The SV, then, constitutes the pacemaker of these hearts. The SV has been lost as a separate chamber in the mammalian heart, but is retained functionally as the sinoatrial (SA) node in the atrium near the point where the *vena cava* enters (Kardong, 2002). This nodal tissue is histologically quite distinct from other cardiac tissue, and retains its role as the dominant pacemaker (Irisawa *et al*., 1993). Infarct or other damage to the SA node results in serious pacemaking issues. There are other nodes and tissues that differ distinctly from the rank and file cardiac muscle cells, but the SA node is the primary area where the beat originates. Purkinje fiber cells serve a nerve-like function in transmitting the beat information through the entire heart, for example, and ionic currents in these cells have also been studied thoroughly. But, given that they do not constitute a spontaneous pacemaking system, nor are homologous structures found in insects, this rich topic further will not be discussed.

The ionic currents, the population of ion channels responsible for them, and their electrical and chemical interactions constitute the pacemaker. These are still not completely understood, nor have all the channels been identified molecularly. Essentially, however, the basic components are known across classes. In other excitable cells, like neurons, there is a negative resting potential of around -70 mV (Alberts *et al*., 2002). When the system is disturbed, for example, by some depolarizing input, an action potential is generated consisting of a wave of depolarization caused by an inward sodium current (Hille, 2001). This traveling wave passes down the axon. The membrane quickly repolarizes to its resting potential and enters into a refractory period, which prevents retriggering by the receding wave.

Cardiac pacemakers, however, have no true resting state as they never hold still (Baumgarten and Fozzard, 1992). By convention, the "resting potential" of true pacemaking cells is often taken to be the most negative potential the system reaches in its cycle, but this is not even a "metastable" state and the cell is at this potential only as it passes through it unless held by voltage clamp. It is possible to find a clamping voltage in pacemaker cells in which little current is elicited, and this may be taken as a resting potential as well (Irisawa *et al*., 1993).

In the simplest case, one may construct a useful "Gedankenschrittmacher," or "thought pacemaker" in a generic heart consisting of a collection of interacting ion channels. Beginning at an arbitrary phase in the cycle, assume an outward cation current that hyperpolarizes the cell. This might be the end of the repolarizing current. Next, add a channel that responds to hyperpolarization in this potential range by opening to a specific cation (or mixture of cations) that is more concentrated extracellularly. The result of this inward cation current must perforce be a rise in intracellular voltage towards some triggering potential. This crucial current is defined to be the pacemaker current. Once voltage reaches this threshold, a second inwardly moving cation current very rapidly depolarizes the cell in a characteristic "action potential" not dissimilar to the axonal spike. The difference lies in the species of ions contributing to the currents. There follows a likewise similar repolarization phase brought about by an outwardly directed cation current. This repolarization sets the system up for the next cycle and may actually contribute to the current starting it. Studies on vertebrates have yielded a considerable amount of information, which yields models that are variations on this simplistic one. The specifics vary across the classes, and even within them, but models such as the one above generate testable hypotheses and serve as a framework to be fleshed out with data.

Owing to the difficulties in studying the electrophysiology of single cardiac myocytes, especially those in the pacemaker, a great deal of the early work was done using microelectrodes in tissues other than the SV or atrioventricular (AV) node. An important distinction must be made between the electrophysiology of the true pacemakers and that of other downstream myocardial cells. The trigger to beat starts in the pacemaker and is distributed to the rest of the heart through tissue specifically dedicated to this task. The signal is termed the cardiac action potential, and can be studied conveniently in tissues such as the Purkinje fibers or even cells of the ventricle. The cells can be distinguished histologically and, critically, the profiles of the ionic currents are different in several crucial aspects. True pacemaker cells have four distinguishing characteristics: (1) they have spontaneous activity; (2) there is no inward rectifying K^+ current; (3) they are insensitive to tetrodotoxin (TTX); and (4) they are sensitive to Ca^{2+} channel blockers (Irisawa *et al*., 1993).

The final event in the process is excitation contraction (EC) coupling, the process by which the internally transported cardiac action potential causes the actual power stroke in the appropriate contractile portion of the myocardium (Bers, 2001). The complexity of the vertebrate EC system is beyond the scope of this work. Fortunately, the problem is considerably more tractable in insects given the straightforward topology of their hearts.

There are two major classes of ionic currents in SA nodal cells depending on whether they are time dependent or independent (Irisawa *et al.*, 1993). Time dependent currents are mediated by gated ion channels carrying Na^+ (I_{Na}), Ca^{2+} ($I_{Ca,L}$ and $I_{Ca,T}$), K^+ (I_K and $I_{Ca,K}$), and a mixture (I_f or, variously, I_h) (Hille, 2001). The nomenclature varies among authors. Ion pumps create the two time invariant currents; one exchanges three inward traveling Na^+ ions for a single Ca^{2+} yielding a net inward cation current (I_{NaCa}), and the other exchanges two inward traveling K^+ ions for three outward moving Na^+ ions (I_{NaK}) (Irisawa *et al.*, 1993). There is another potentially important background depolarizing Na^+ "leak" current, I_{bNa} (Giles *et al.*, 1982).

2.6.3.1.1.1. I_{Na} The role of sodium channels (see **Chapter 5.1**) in pacemaking is problematic, given that true pacemaker cells are TTX insensitive, whether vertebrate or invertebrate (Irisawa *et al.*, 1993). There are reports, however, that some individual SA node cells have a portion of their action potential sensitive to TTX (Denyer and Brown, 1987). One of the central pacemaking currents may be a mixed one, passing through a channel that is not completely selective. The role of Na^+ in other myocardial tissues in vertebrates is central, but this topic will not be considered further.

2.6.3.1.1.2. I_{Ca} Two distinct Ca^{2+} currents, carried by different channels, contribute to the cardiac action potential. The larger is termed L type, owing to its current being relatively Long-lived and Large ($I_{Ca,L}$) and the other Tiny and Transient (I_{Ca},T; Hille, 2001). The channels may be separated on the basis of pharmacology as well as kinetics. L-type channels are sensitive to 1,4-dihydropyridines (DHP; nifedipine, for example). The therapeutic calcium channel blockers verapamil and diltiazem selectively block L-type conductances (Hille, 2001). One view of the cooperative role of these two types of Ca^{2+} channels in pacemaker cells is that $I_{Ca,T}$ seems to be active for a short period of time during the first part of the action potential or major spike of rising voltage, carrying the membrane to the voltage range at which $I_{Ca,L}$ activates and does the heavy lifting in the spike (Hagiwara *et al.*, 1988).

In addition to the flow of Ca^{2+} down its gradient from the relatively more concentrated extracellular regions, there is recent evidence that calcium plays another, qualitatively different role in triggering the pacemaker (Lipsius *et al.*, 2001). The observation that ryanodine causes a lowering of diastolic depolarizing current in the SA node (Rigg and Terrar, 1996; Li *et al.*, 1997; Rigg *et al.*, 2000; Terrar and Rigg, 2000) implicated this release in SA node pacemaking. Ryanodine selectively inhibits release of calcium from the sarcoplasmic reticulum (Rousseau *et al.*, 1987). Release appears to be triggered by $I_{Ca,T}$ based on the low-voltage range (lower than L-type) in which the calcium release is seen and the inhibition of the observed release when T-type channels are blocked specifically by Ni^{2+} (Hagiwara *et al.*, 1988; Hüser *et al.*, 2000). The contribution of this release is thought to be stimulation of the net inward current of the sodium/calcium exchanger ($I_{Na–Ca}$), further depolarizing the plasma membrane, perhaps sufficiently for depolarization. The effect is more pronounced in latent, as opposed to working, pacemaker cells of the SA (Hüser *et al.*, 2000).

2.6.3.1.1.3. I_K K^+ plays a central role in the repolarization of the membrane after the calcium spike in the same manner as seen in neurons (Gintant *et al.*, 1992). In the heart, there are two major subcategories of channels, with the distinction based on differing activation modes. The first consists of voltage-activated gating. As the potential rises above threshold, the channels open permitting outward flow of K^+ along its concentration gradient. The second category consists of channels gated on the cytosolic side by Ca^{2+} sensing. Given that the cardiac action potential results from a calcium spike, this is a crucial step. The inrush of calcium would trigger the repolarization in consort with the voltage-gated K^+ channels. These calcium-activated potassium channels (CaKs) appear to play a central role in the early stages of the repolarization (Gintant *et al.*, 1992). The current responsible for this early phase of repolarization has been commonly referred to as the transient outward potassium current (I_{to}) (Gintant *et al.*, 1992). A second role for K^+ flux is discussed below with regard to the pacemaker currents.

2.6.3.1.1.4. I_f I_f is the "funny current," also called the hyperpolarization-activated current, or I_h (*inter alia*). It has been identified in some but not all pacemaker cells, and its role remains somewhat controversial (DiFrancesco, 1993). One early hypothesis for

the nature of the "pacemaker current" was that decay of the outward potassium current at the end of repolarization, against a constant inward leak current (for example, a background Na^+ current), could result in the gradually rising net inward current that ultimately starts the two-stage depolarization of the Ca^{2+} spike (DiFrancesco, 1993; Irisawa *et al*., 1993). However, several workers have reported reliable recordings of a separate slow depolarizing current, most likely carried by a combination of both Ca^{2+} and Na^+, that fulfils the definition of a true pacemaker current. It is activated when the membrane is hyperpolarized, and depolarizes the cell to the point where T-type Ca^{2+} channels open to start the spike of the action potential (Van Ginneken and Giles, 1991; Moroni *et al*., 2001).

2.6.3.1.2. Insect hearts Insect hearts are simple tubular structures that beat peristaltically to circulate hemolymph. The beat consists of a contraction phase (systole), followed by relaxation (diastole), and in some insects, there is a rest period (diastasis) preceding the next systole (Jones, 1977; Rizki, 1978). The pacemaker is myogenic, but there has been confusion on this issue. *Limulus* has been used as the perfect example of a neurogenic arthropod heart, and unfortunately, was taken to be the model for all arthropods (Prosser and Brown, 1961; Wiggelsworth, 1965). For some time, insect hearts were assumed to be generally neurogenic (Miller, 1985). A popular insect that was used to tackle the problem of myogenicity versus neurogenicity was the cockroach, *Periplaneta americana*, but this proved an unfortunate choice as its heart is heavily innervated (Alexandrowicz, 1926; McIndoo, 1945; Miller, 1969). It was initially thought to be neurogenic, owing largely to the presence of this nervous tissue, but also to pharmacological evidence (Jones, 1977). Krijgsman and Krijgsman-Berger (1951) prepared isolated, perfused *P. americana* hearts that retained their closely associated putative pacemaker ganglia and exposed them to a wide array of substances with known effects on vertebrate cardiac preparations. Caffeine, which stimulates the vertebrate heart, inhibited that of the cockroach, while digitalin, which has no effect on the vertebrate heart, was found to be acceleratory. Similarly, acetylcholine (ACh) slows the vertebrate heart but accelerates the heart rate in their insect tests. Given these responses, it was concluded that the pacemakers of vertebrates and cockroaches must be fundamentally different, and that of the latter (and by extension, that of other insects) must reside in the associated ganglia.

Insect hearts, however, have been found to be myogenic. Evidence of myogenicity is straightforward and unequivocal and comes from a number of experimental approaches (Miller, 1985). If practicable, demonstration of continued heartbeat after surgical ablation of any innervation that might contribute to pacemaking is telling. This was successfully done in *P. americana* despite its extensively innervated heart (Miller, 1969). The rate of isolated cockroach hearts continues to respond to exogenously applied cardioactive neurotransmitters like Ach and norepinephrine, indicating that not only is the pacemaker myogenic, but that some control is possible in the absence of innervation (Miller, 1969). Early work on the moths *Hyalophora cecropia* (Sanger and McCann, 1968a, 1968b) and *Manduca sexta* (Tublitz, 1988) reported a complete lack of cardiac innervation. Given that neural control of reversal of heartbeat in *Manduca* has been reported (Dulcis *et al*., 2001), clearly some innervation must exist in that animal, and this has been delineated using modern neuronal tracing techniques (Davis *et al*., 2001). However, evidence of neuronal control is not evidence of neurogenicity, and continued normal beat in the near or complete absence of intact cardiac neuronal structures strongly supports myogenicity (McCann, 1970). In *Drosophila*, which is intermediate in the extent of its innervation (Rizki, 1978; Dulcis and Levine, 2003), surgical removal of all cardiac nerves allows the beat to continue unchanged (Miller, 1950), but "twigs" of remaining axons cannot be ruled out as the source of the beat, rendering surgical evidence not entirely conclusive in this species (Rizki, 1978).

A second line of investigation utilizes pharmacology. The substance procaine is a powerful inhibitor of nerve function (Taylor, 1959; Hille, 1966), but perfusion of the cockroach heart with this substance does not affect the beat (Maloeuf, 1935) and this should have settled the matter at the time. The specific and highly effective blocker of Na^+ channels, TTX (Narahashi *et al*., 1964), is also without effect on the cockroach heart (Smith, 1969), providing a very powerful argument against neurogenicity in this heavily innervated heart. These results were repeated recently in *Drosophila*, thereby reinforcing Rizki's (1978) earlier interpretation of myogenicity in this animal (Dowse *et al*., 1995; Gu and Singh, 1995).

Manipulation of ion concentration in the perfusates of isolated hearts has been informative concerning potential pacemaking mechanisms. Various moths have been useful in these studies. The hemolymph of Lepidoptera is low in Na^+ (Carrington and Tenney, 1959; McCann, 1963) and the animals

are large and easily manipulated. McCann (1963) studied the electrophysiology of *Telea polyphemus* while varying the concentration of Na^+, K^+, Ca^{2+}, and Mg^{2+} bathing the isolated hearts. Even in the complete absence of Na^+, there was no interference with normal beating. In contrast, heart rates of both *T. polyphemus* (McCann, 1963) and *H. cecropia* (McCann, 1971), were shown to be sensitive to changes in Ca^{2+} concentration, leading to the conclusion that the myocardial action potential depends on a calcium spike rather than the typical Na^+ based neuronal action potential (McCann, 1971).

Differential effects of ACh and epinephrine have long been regarded as diagnostic in discerning myogenic versus neurogenic pacemakers, but this has turned out to be unreliable (McCann, 1970). The widely held belief was that epinephrine would accelerate both myogenic and neurogenic pacemakers, but that acetylcholine would accelerate and decelerate the neurogenic and myogenic activity, respectively. In insects, this breaks down. ACh accelerates some insect hearts, e.g., that of *Drosophila* (Johnson *et al.*, 1997, 2002), while decelerating that of *Manduca* (McCann, 1969). The effects of ACh in *Drosophila* are particularly provocative. It requires two orders of magnitude higher concentration of ACh than norepinephrine to achieve the same minimal threshold response (Johnson *et al.*, 1997), and ACh is without effect even at very high concentrations in flies bearing the temperature-sensitive *paralytic* (*para^{ts}*) mutation (Suzuki *et al.*, 1971) (see below for details on this mutation) held above the restrictive temperature, which eliminates Na^+ based action potentials. This implies that the effect of ACh is mediated through the nervous system (Johnson *et al.*, 2002). Co-injection of TTX also negates any effect of ACh (E.C. Johnson, unpublished data). Effects of norepinephrine are unaltered by the *para^{ts}* mutation (Johnson *et al.*, 2002).

In *Drosophila*, genetics offers a direct molecular approach in the form of ion channel gene mutants. Dowse *et al.* (1995) tested the mutant *para^{ts}*, which encodes a sodium channel (Loughney *et al.*, 1989). At restrictive temperatures, all sodium-dependent action potentials cease owing to a reversible change in a subunit of the essential conducting channel (Suzuki *et al.*, 1971). Adult flies pass out at this temperature, but revive when cooled back to permissive levels (Suzuki *et al.*, 1971). The heart, however, is unaffected in these animals at the restrictive temperature. This observation, along with that of the TTX application, strongly supports the argument for a myogenic origin of the beat in this organism (Dowse *et al.*, 1995).

Electrophysiology has been employed to characterize pacemaker types. The well-known neurogenic heart of *Limulus* is fairly representative of this type of pacemaking system (Prosser, 1973). Bursts in the cardiac pacemaking ganglia precede systole and subside during diastole. This makes sense, given that the ganglia are signaling the myocardium to contract and coordinating the beat process. In the cockroach, however, three things may be recorded depending on timing and conditions. First, the heart may be seen to beat when there is no activity in the ganglia whatsoever. Second, the activity in the ganglia may be intense, but not coordinated with the beat in any meaningful way. Third, there may be overt synchrony, but this will occur during diastole, not systole. The interpretation of this is that the ganglia are actually responding to the heart's autonomous beat by a burst of activity resulting from a stretching of the nerve tissue by the physical movement of the myocardium (Prosser, 1973; Jones, 1977; Miller, 1985). Recordings of electrical activity in the insect myocardium itself are similar to classical myogenic action potentials in the vertebrate heart. Rather than the clustering of spikes seen prior to systole in the pacemaking ganglion typical of *Limulus*, insect hearts show a slow rising pacemaker potential leading to a single, relatively long-lived action potential spike (McCann, 1963; Rizki, 1978; Miller, 1985).

This typical pattern can be seen in insects across all levels of cardiac innervation. The highly innervated heart of *P. americana* still produces a depolarizing pacemaker potential leading to a long-lived action potential, followed by a refractory phase (Miller, 1985). The least innervated heart commonly studied is that of *H. cecropia* (Sanger and McCann, 1968a, 1968b; McCann and Sanger, 1969). Recordings from single myocardial cells in *H. cecropia* yield the significant observation that individual cells could produce a range of action potential profiles depending on the depolarization imposed on them (McCann and Sanger, 1969). In an extensive study of the mealworm beetle, *Tenebrio molitor*, recordings from the myocardium yield typical myogenic patterns (Markou and Theophilidis, 2000). Johnson *et al.* (2001) demonstrated simple two-electrode electrocardiograms of *Drosophila*. Though these do not have the resolution of individual cell recordings, they clearly indicate myogenicity, lacking any sharp bursts correlated with contraction as is found in the neurogenic condition. A useful preparation for monitoring the isolated heart of *Drosophila* has been reported by Papaefthimiou and Theophilidis (2001) with the same pattern being evident.

2.6.3.1.2.1. Pacemaker location The hearts of vertebrates are arranged in a hierarchy, with the SA node cells, or at least a subpopulation thereof, setting the beat for the rest of the myocardium

(Irisawa *et al.*, 1993). This appears not to be the case in insects. Distinctive nodal tissue remains unreported in histological studies of insect hearts (see, for example, Sanger and McCann, 1968a or Curtis *et al.*, 1999). Functional approaches suggest that all of the heart proper may function to generate a beat in many insects. In *T. polyphemus*, all heart regions tested, under appropriate circumstances, demonstrate the classic pacemaker potential that confers automaticity (McCann, 1963). This implies that in the moth, the myocardium generally can act as a pacemaker, and that such activity is not localized to a specific node-like region. In *T. molitor*, when the heart is sectioned, each segment retains intrinsic rhythmicity in isolation. However, the *Tenebrio* aorta, unlike that of *Manduca*, contains no self-sustaining pacemaker function (Markou and Theophilidis, 2000).

Despite this evidence of anatomical and histological homogeneity of pacemaking, there are reports that suggest that some specialization exists. As detailed below, injection of the L-type calcium blockers verapamil or diltiazem appears to stop contractions in the myocardium in general, while leaving beat in a caudal section of the heart unaffected (Johnson *et al.*, 1998). This implies that there is a different population of ion channels in the two regions and that the most caudal region may serve as a "master pacemaker."

Functional localization of discrete pacemaker regions is also suggested by a peculiarity of insect hearts, namely the observation that the direction of the peristaltic wave that constitutes diastole can reverse direction (Jones, 1977). This has been noted across a wide range of insects. The implication is that there must be two distinct pacemaker regions that can alternate dominance and must be coordinated. Jones (1977) mentions a remarkable example of beats initiating at both ends of the heart simultaneously, with the resultant waves meeting in the middle and canceling each other out. This process is likely to be under neural control at some level, to account for the coordination of pacemakers. Reversal is often seen to result from some external cue, such as behavior (Kuwasawa *et al.*, 1999). One common thread may be alterations in gas exchange patterns as the hemolymph flow changes direction (Wasserthal, 1981, 1996). Birchard and Arendse (2001) applied an allometric analysis to relate respiration with cardiovascular function. Despite the obvious lack of oxygen-carrying pigments in insect hemolymph, measurements of critical heart parameters like rate and cardiac output scaled linearly with oxygen consumption, with nearly the same exponent, providing further circumstantial evidence of a functional relationship (Birchard and Arendse, 2001). Neural control of pacemaker dominance has been well documented in several instances, with *M. sexta* being a major contributor in these studies. Dulcis *et al.* (2001) used electrocardiograms to document changes in heart function in larvae, pupae, and adults of this moth. Their findings in larvae corroborated earlier work in that only anterograde pacemaking occurred (Platt and Reynolds, 1985; Smits *et al.*, 2000). In early pupae, however, they saw reversals, with rapid anterograde pulsing alternating with slow retrograde. In all cases, the pupal heart rate was slower than that found in the adult. By treating the preparations with TTX, they were able to show both that the beat was myogenic, (clearly no surprise) but the elimination of Na^+ dependent action potentials eliminated the alternation between anterograde and retrograde, leaving only the slow retrograde. Surgical section of the nerves to the posterior portion of the heart mimicked the effects of TTX, leaving only the anterior pacemaker active. Stimulation of this nerve could be used to control the reversals as well (Dulcis *et al.*, 2001). Thus, although the entire myocardium may be generally capable of pacemaking, discrete regions may be dominant.

2.6.3.1.2.2. Electrogenesis of the pacemaking signal Given that the origin of heartbeat in insects is myogenic, a major concern is the electrogenesis of the pacemaker and action potentials in the myocardium. The ultimate elucidation will culminate with the identification and biophysical characterization of the ion channels involved, the genes encoding them, and the specific splice variants represented in the pacemaker tissue. A great deal of general cardiac physiology has been previously done in a range of insects, most notably *Periplaneta, Manduca,* and *Hyalophora*, which gives a good basic understanding of the ion species involved and their conduction kinetics (McCann, 1970; Miller, 1985). Determining which ion species are involved in the cardiac pacemaker and action potentials is a good place to start. This can be done by straightforward manipulation of concentration in the perfusate bathing isolated hearts. One obvious possibility is that the pacemaker is Na^+ dependent, given the ubiquitous nature of sodium inward currents in action potentials in the nervous system. The work described above to determine whether the pacemaker is neurogenic clearly eliminates this possibility. Insect pacemakers turn out not to be Na^+ dependent (McCann, 1963, 1969; McCann and Sanger, 1969; Miller, 1985), and this matches precisely the findings in mammals (Irisawa *et al.*, 1993).

Based on extensive work on the vertebrate heart, a prime candidate is Ca^{2+} (Irisawa *et al.*, 1993). McCann (1971) demonstrated Ca^{2+} spikes in *H. cecropia* by showing a relationship between cardiac action potential levels and Ca^{2+} concentration. With calcium-free perfusate, the action potential quickly drops to zero. In further support of this, replacement of Ca^{2+} with Mn^{2+} in the perfusate also quickly abolished excitability in the cells. K^+ is a second possible candidate. McCann (1963), working with *in situ* hearts of *T. polyphemus* that had been decapitated and had the mesothoracic ganglion removed, determined that varying the concentration of K^+ in the perfusate could affect heart rate.

In order to establish the ionic mechanism of the insect pacemaker, a test organism that can facilitate such studies is required. Given the clear advantages of working with *D. melanogaster* in unraveling cellular and molecular mechanisms, it is surprising that work on its heart only began in earnest in the mid 1990s. In 1978, Rizki published a thorough monograph, covering the anatomy, histology, composition of the hemolymph, and physiology in *Drosophila*. In this work, the question of myogenic versus neurogenic arose; however, Rizki did not attempt to settle it, but simply noted that the beat was probably myogenic, given that physical isolation of the heart did not cause it to cease beating, but that the process of reversal suggested some neural control. He also reported on the temperature dependence of the *Drosophila* heartbeat, but did not speculate on its cause (Rizki, 1978).

Drosophila cardiac physiology was not investigated further substantively until the work of White *et al.* (1992). Given the linearly dose-dependent effect of deuterium oxide ("heavy water" or D_2O) in slowing the circadian clock (Edmunds, 1988), these investigators looked at its effects on heart rate and their interactions with temperature. The choice was made to observe only very early stage pupae for this (and later studies from this laboratory cited here), owing to the ease with which heartbeat could be monitored with a noninvasive optical system (Dowse *et al.*, 1995; Johnson *et al.*, 1997, 1998). Flies were raised on medium containing various concentrations of D_2O and the rate was measured over a range of temperatures. In this work, the data were analyzed using current digital signal analysis techniques, including maximum entropy spectral analysis (MESA) (Burg, 1967; Ulrych and Bishop, 1975) and signal-to-noise ratio (SNR) programs specifically adapted by one of the authors for biological time series (Dowse and Ringo, 1989; review: Levine *et al.*, 2002). This allowed precise estimates of heartbeat frequency and regularity. The authors discovered that D_2O decreased heart rate in a dose-dependent fashion, but noticed a curious interaction between temperature and deuterium concentration. There was a flattening of the slope relating heart rate to temperature as the concentration of D_2O was raised, suggesting that the heart was not as sensitive to changes in temperature when deuterated. Unfortunately, owing to the multiple effects of heavy water on cellular processes, no firm conclusions could be drawn regarding the mechanism of the pacemaker or its control (White *et al.*, 1992).

Immediately, further studies appeared that applied a combination of genetics and pharmacology to unraveling the ionic basis of the pacemaker and its control. Dowse *et al.* (1995) began by searching for mutants that affected heart rate or regularity from among a large group of candidates including those displaying neurological and behavioral phenotypes. Among these were lesions in genes encoding ion changes. The pupal preparation described in White *et al.* (1992) was employed here, with the addition of a new method of quantifying rhythmicity. The height of the third peak of the autocorrelation function was taken as the "rhythmicity index" (RI). The decay envelope of this function is a reliable estimator of long-range regularity in a rhythmic time series (Chatfield, 1980; Levine *et al.*, 2002). Among these were lesions in genes encoding ion channels. The first *bona fide* heart temperature-sensitive mutant to surface was *no action potential* (*nap^{ts}*) (Wu *et al.*, 1978; Dowse *et al.*, 1995). This had originally been thought to encode a Na^+ channel, but turned out to be a regulatory gene controlling, among other things, the gene *$para^{ts}$* via a splicing catastrophe (Suzuki *et al.*, 1971; Wu *et al.*, 1978; Ganetzky *et al.*, 1984; Jackson *et al.*, 1984; Loughney *et al.*, 1989; Reenan *et al.*, 2000). In testing *$para^{ts}$* itself, it turned out to have no effect on heart rate or regularity (Dowse *et al.*, 1995). This finding further established the myogenicity of the *Drosophila* heart, but also begged the question of what exactly *nap^{ts}* was doing to the heart (Dowse *et al.*, 1995). The hearts of mutant flies were arrhythmic compared to wild-type at all temperatures, and this irregularity increased with temperature. A curious fact emerged, and that was that *nap^{ts}* hearts were less able to track increases in temperature, barely increasing frequency at all over more than a 10 °C range. This is most curious, as heart rate in poikilotherms is closely tied to temperature, and the physical chemistry of the oscillating system demands an alteration in rate. Yet no change occurs.

K^+ channels have been firmly established as components of the *Drosophila* pacemaker. Tetraethylammonium (TEA), a general inhibitor of K^+

channel function (Gho and Mallart, 1986), slows the heart (Gu and Singh, 1995; Johnson *et al.*, 1998), but this substance affects all four known subgroups of K^+ currents in larval and adult muscle. There are two Ca^+ activated currents, fast (I_{CF}) and one slow (I_{CS}), and two voltage activated currents, fast (I_A) and slow (I_K) (Singh and Wu, 1989). These currents and the responsible channels can be separated by combining pharmacology and genetics (Singh and Wu, 1989). To do so for the heart pacemaker, an initial genetic screen yielded three channels as candidate pacemaker components, all of which pass K^+ ions (Johnson *et al.*, 1998). The most profound K^+ channel mutation affecting the heart is *slowpoke* (*slo*) (Elkins *et al.*, 1986). Flies bearing this mutation have almost nonexistent heartbeat, and such rate as may be discerned does not increase with temperature as was found with nap^{ts}. *slo* encodes the pore forming subunit of a Ca^{2+} activated K^+ (CaK) channel (Atkinson *et al.*, 1991) and interferes specifically with I_{CF} (Elkins *et al.*, 1986). Such channels have been implicated in repolarization in the vertebrate heart pacemaker (see above). To cross-check this finding, pupae were injected with charybdotoxin (CTX), a specific blocker of CaKs, and the result was exactly as was seen in the mutants, i.e., extreme interference with heart function (Johnson *et al.*, 1998).

Two other mutants turned up as candidates. The first, *ether-a-go-go* (*eag*), encoding a voltage-gated K^+ channel (Wu *et al.*, 1983; Warmke *et al.*, 1991; Zhong and Wu, 1991), affects all four currents and makes the heart beat slightly more slowly and irregularly than in the wild-type (Johnson *et al.*, 1998). The final candidate, *Shaker* (*Sh*), encodes another voltage-gated K^+ channel (Salkoff and Wyman, 1981; Singh and Wu, 1989) and turns out to be extremely interesting, in that it renders heartbeat more rapid and rhythmic than in the wild-type (Johnson *et al.*, 1998). Other K^+ channel blockers had minimal effect (Johnson *et al.*, 1998).

Chief among the missing components, based on the vertebrate model, are voltage-gated Ca^{2+} channels. Manipulation of Ca^{2+} concentrations in insect hearts (see above) demands their participation. Gu and Singh (1995) found that the L-type calcium channel blockers verapamil and diltiazem affected heart rate in their preparations. Johnson *et al.* (1998), using an optical monitoring system on intact pupae, as well as semi-isolated perfused pupal heart preparations, found that the two blockers had no effect on heart pacemaker rate or rhythmicity. However, the interesting observation was made that while the posterior region of the heart continued to function normally, the rest of the myocardium did not (see above). This leaves open the provocative possibility that either EC coupling is disrupted, or that L-type channels are necessary for the action potential in the bulk of the heart muscle, while there is a separate true pacemaker located posteriorly that is responsible for generation of the beat. The rest of the heart may be able to beat on autonomously, but requires this unique pacemaker tissue for normal heart rate and rhythmicity. This would be analogous to the SA nodal tissue in mammals. No histologically unique tissue could be discerned in this area (Curtis *et al.*, 1999).

Participation of a non-L-type calcium channel was discovered pharmacologically using a toxin from a piscivorous snail, ω-conotoxin VIIC (ω-CgTx), which targets precisely a non-L-type voltage-gated K^+ channel (Olivera *et al.*, 1994). This toxin renders the *Drosophila* pupal heart almost totally inactive at very low doses (Johnson *et al.*, 1998). Pharmacology, however, does not easily deliver the targeted channel molecularly. Thus, genetics remains as the path to the final piece in the puzzle.

Two Ca^{2+} channels currently under study are likely candidates for playing a role in heart function. The first is an L-type channel, and thus is a likely contributor to the action potential in the myocardium generally. It is encoded by the *calcium channel alpha1D* subunit (*DmCa1D*; Eberl *et al.*, 1998), and is DHP sensitive, hence predictably L-type in its kinetics (Eberl *et al.*, 1998), it is a bona fide heart mutant. Flies homozygous for the allele *AR66* live until the early pupal stage, and may be tested for heart function in the usual manner, though they die before eclosion. Such flies have an aberrant heartbeat (E.C. Johnson and H. Dowse, unpublished data). The second is a DHP-insensitive Ca^{2+} channel named DmCa1A, the α1 subunit of which is encoded by the gene *cacophony* (*cac*) (Schilcher, 1976, 1977; Smith *et al.*, 1996). Two *cac* alleles, cac^S (for *cac-song defective*), originally uncovered by Schilcher (1976, 1977) and cac^{ts2} (*temperature sensitive 2*) (Dellinger *et al.*, 2000), affect the pulse component in the *Drosophila* mating song, causing several extra oscillations in each pulse (Schilcher, 1977; Kulkarni and Hall, 1987). The *cac* alleles both affect the heart in an unusual way, but one that makes sense in light of what is observed in the song pulses. The heart beats more rapidly and more regularly than wild-type, especially at high temperatures (V. McGowan and H. Dowse, unpublished data).

The results of this genetic and pharmacological identification of essential pacemaker ion channels suggested a simple model for the *Drosophila* pacemaker (Johnson *et al.*, 1998). A leaky cation channel would cause slow depolarization, i.e., the

pacemaker current, enough to trigger a Ca^{2+} spike, the main outward current of the action potential. This inrush of Ca^{2+} would trigger a calcium-activated K^+ channel (e.g., *slo*?), causing delayed repolarization of the membrane and return to the "resting potential." Such a model is not dissimilar to one proposed for generation of the pulse in *Drosophila* song involving the same ensemble of ion channels (Peixoto and Hall, 1998). Without the leak pacemaker current to confer automaticity, an oscillator constituted in this way has been delineated in the vertebrate ear. Oscillatory interactions between voltage-gated Ca^{2+} channels and Ca^{2+}-gated K^+ channels underlie the resonant response to sound in the vertebrate hair cell (Art and Fettiplace, 1987; Hudspeth and Lewis, 1988a, 1988b), and frequency response has been attributed to the differential expression of Ca^{2+}-gated K^+ channel isoforms along the length of the cochlea (Rosenblatt *et al.*, 1997; Black, 1998; Jones *et al.*, 1999). It is hypothesized that this gradation is the substrate for frequency resolution atleast lower in lower vertebrate hearing (Rosenblatt *et al.*, 1997; Black, 1998; Jones *et al.*, 1999).

The Johnson *et al.* (1998) model has received experimental support from Markou and Theophilidis (2000) working with *T. molitor*. These workers depleted Ca^{2+} in the perfusate of isolated hearts and found that not only did the heart stop beating, but it also entered a state of depolarization. As soon as Ca^{2+} was added to the perfusate, the heart cells immediately repolarized and regained oscillatory function. The interpretation was that Ca^{2+} was needed to trigger the K^+ current through a CaK channel enabling repolarization.

Mathematical modeling of this simple scheme confirms that these components are capable of generating autonomous oscillations (S. Crook, unpublished data). **Figure 8** illustrates the currents required by the model, with an outward leak current (I_{lk}) that serves as the pacemaker current needed for automaticity, an inward calcium-spike (I_C), and the repolarizing outward potassium current triggered by rising intracellular calcium concentration (I_{K-Ca}).

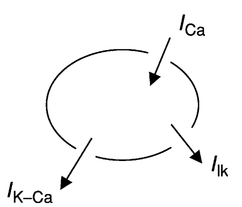

Figure 8 Diagrammatic summary of the currents needed for the *Drosophila* pacemaker model delineated by Johnson *et al.* (1998). See text for details.

A Hodgkin Huxley-type model was implemented in Simulink (S. Crook, unpublished data).

The following equations describe the ionic currents; the parameters denoted by g represent the maximal conductances for each current, which are determined by the density of ion channels, while the parameters denoted by E represent the reversal potentials for each current:

$$I_{K-Ca} = g_{K-Ca} r(v - E_K)$$
$$I_{Ca} = g_{Ca} qp(v - E_{Ca})$$
$$I_{lk} = g_{lk}(v - E_{lk})$$

From these current relationships, the following equations were derived to create the model pacemaker:

$$\frac{dv}{dt} = -I_{K-Ca} - I_{Ca} - I_{lk} \quad [1]$$

$$\frac{dc}{dt} = -\alpha I_{Ca} - \beta c \quad [2]$$

$$\frac{dq}{dt} = \frac{q_\infty(v) - q}{\tau_q(v)} \quad [3]$$

$$\frac{dp}{dt} = \frac{p_\infty(v) - p}{\tau_p(v)} \quad [4]$$

$$\frac{dr}{dt} = \frac{r_\infty(c) - r}{\tau_r(c)} \quad [5]$$

The following are state variables in the system: v, membrane potential; c, the concentration of intracellular Ca^{2+}; q, p, gating variables representing the voltage dependent activation and inactivation (respectively) of the Ca^{2+} channel; and r, the Ca^{2+} dependent activation of the K^+ channel.

The model equations include a current balance equation (eqn [1]) describing membrane potential change over time and how the changes depend on ionic currents including the leak current. Equation [2] describes the change in $[Ca^{2+}]$ with time. Ca^{2+} is removed by membrane based pumps with a rate proportional to intracellular $[Ca^{2+}]$. Equations [3]–[5] describe the change of the gating variables in time as voltage- and calcium-gated channels activate and inactivate. In eqs [3]–[5], the curves denoted by "∞" represent the steady-state activation or inactivation curves for each gating variable and the τ curves represent time constants for reaching those steady-state values as voltage or Ca^{2+} varies. The simulated model voltage trace shown in **Figure 9** shows that membrane potential in the system is spontaneously oscillatory.

Internal release of calcium from ryanodine receptors has also been implicated in heart function,

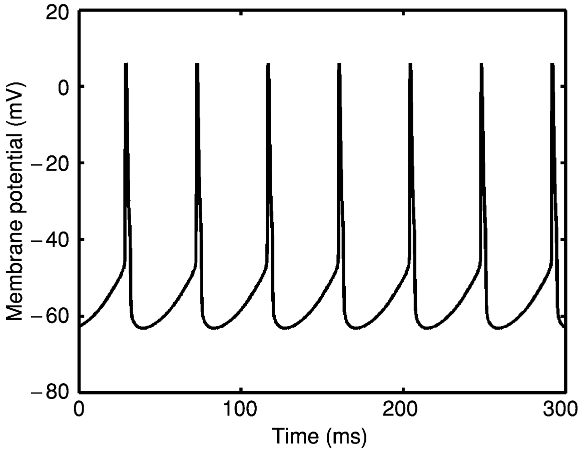

Figure 9 Output of the model demonstrating self-sustained pacemaker-like oscillatory behavior.

potentially in the pacemaker. The *Ryr[16]* mutation slows heartbeat substantially in all three larval stages (Sullivan *et al.*, 2000), and injection of ryanodine is also effective in slowing heart rate in larvae (Sullivan *et al.*, 2000) and pupae (E.C. Johnson and H. Dowse, unpublished data). Coupled with this, interference with normal levels of cytoplasmic Ca^{2+} by lowering sequestration rates into the sarcoplasmic reticulum also causes what appears to be pacemaking problems. A mutation that effects a decrement in function in the *s*arcoplasmic/*e*ndoplasmic *r*eticulum *ca*lcium ATPase (SERCA) causes severe disruption of heart function (M. Ramaswami, S. Subhabrata, and H. Dowse, unpublished data). One allele, *kumbhakarna* (*kum[170]*), causes almost total cessation of heartbeat after a 41 °C heatshock.

2.6.3.1.3. Broader applicability of the insect findings Elucidation of the pacemaker ion channels in insects may have a direct bearing on matters of human health. The gene *eag* was initially discovered in *Drosophila* (Catsch, 1944; Kaplan and Trout, 1968). The cDNA from this gene was used to detect a closely related channel in mammals: human ether a go go related gene (HERG) (Warmke and Ganetzky, 1994). HERG was ultimately shown to be a homolog of the *Drosophila* gene *seizure* (Jackson *et al.*, 1984; Wang *et al.*, 1997). Mutations in HERG result in a cardiac arrhythmicity in humans, chromosome 7-linked long QT (LQT2) syndrome (Keating and Sanguinetti, 1996; Sanguinetti *et al.*, 1996). The HERG channel passes a rapidly-activating, delayed-rectifier current (I_{Kr}), and in individuals carrying the mutation, there is a delay in cardiac repolarization (Curran *et al.*, 1995; Sanguinetti *et al.*, 1995; Sanguinetti *et al.*, 1996). Provocatively, *eag*, causes a congenital defect in the *Drosophila* heart (Johnson *et al.*, 1998).

2.6.3.2. Physiological Basis of Modulation

A requirement of cardiac pacemaking is that it must be flexible, as it needs to adjust cardiac output to meet metabolic demands over a large range of different environmental and behavioral conditions. In insects, multiple functions are associated with heartbeat and while respiration in insects is largely an independent process, the delivery of nutrients and hormones depends upon a functional cardiovascular system. In a number of these poikilothermic animals, heartbeat contributes to the process of thermoregulation (Heinrich, 1970, 1971). Additionally, in the holometabolous insects, the process of adult wing inflation involved in ecdysis behaviors rely upon the mechanical actions of the heart pumping hemolymph (Baker *et al.*, 1999; Park *et al.*, 2003).

The cardiac pacemaker of insects is responsive to changes in temperature, electrochemical gradients, and transmitter titers and alters output to meet different physiological demands. Ultimately, changes in heart rate are mediated through alterations of transmembrane potentials, such as the ones outlined above (Trautwein and Osterrieder, 1986). Some stimuli may mediate these modifications on pacemaker potentials directly, e.g., diffusible transmitters acting upon ionotropic receptors. Other stimuli do so indirectly, through networks of intracellular signaling pathways leading to biochemical modifications of pacemaker components. As discussed above, the pacemaker consists of an ensemble of ion channels, coordinating the rhythmic contractions of the heart through the generation of oscillations in transmembrane potential. Therefore, it follows that any stimulus capable of changing pacemaker output must somehow act upon these electrochemical oscillations. Acceleratory and inhibitory stimuli might alter pacemaker currents through either the addition of novel ionic currents that are normally quiescent, or through the modification of existing currents underlying pacemaker activity.

The authors could extrapolate what has been discovered about the ionic pacemaker to make general assumptions regarding modulatory mechanisms. Acceleratory stimuli must affect these currents predictably; specifically, they must shorten the length of the repolarization or rest phase of pacemaker tissue. By definition, inhibitory stimuli actions must do the opposite. This suggests that different transmitters acting upon the pacemaker in a similar fashion may share common signaling pathways.

2.6.3.2.1. Signaling pathways Ion channels typically contain multiple consensus sites for various modifying proteins, including various kinases and phosphatases, linking them as potential targets of intracellular signaling pathways. For example, the *slo* channel is phosphorylated by the cAMP dependent kinase (PKA), as well as Src tyrosine kinases (Wang *et al*., 1999; Zhou *et al*., 2002); these changes culminate in a decrement in channel activity (Zhou *et al*., 2002). Likewise, another candidate pacemaker channel, encoded by the *eag* gene, is a substrate for calmodulin-CAM-kinase II phosphorylation and this biochemical modification causes a reduction in *eag* current amplitude. In whole cell recordings of the *Drosophila* retina, the biogenic amine serotonin affects the potential at which *Shaker* channels open, and stimulation of G proteins mirrors this effect (Hevers and Hardie, 1995). Calcium channel activity in *Drosophila* is modulated by the activity of PKA and PKC (Gu and Singh, 1997). Unfortunately, technical constraints make it difficult to directly connect a transmitter to an altered pacemaker current. However, pharmacological and genetic approaches have been utilized to implicate signaling pathways that mediate cardiac modulation. Manipulations of G proteins, cAMP, cGMP, and protein kinases through genetic variants and/or pharmacological agents have illuminated some common elements of excitatory and inhibitory modulatory networks.

In *Drosophila*, at least one member of each representative G protein α subunit is present (Gs, Gq, Gi, and Go), as well as β and γ subunits (Wolfgang *et al*., 1990; Quan *et al*., 1993; Talluri *et al*., 1995). Pharmacological agents that discriminate between these G protein subtypes (see **Chapter 5.5**) have been used to assess possible involvement of specific G proteins in cardiac modulation. Cholera toxin, which activates Gs pathways, produces no significant change in heartbeat, while in contrast, pertussis toxin, which blocks receptor-Gi/o protein interactions, significantly increases basal heart rate (Johnson *et al*., 2002). Inhibitory stimuli operate through a pertussis-sensitive G protein subtype and a number of neuropeptides and transmitters have been shown to slow the heart (reviewed below). These effects are potentially mediated through the α subtypes. A candidate gene, $G_{o\alpha}47A$, is expressed in cardiac tissue during development and regulates formation of the cardiac epithelia (Guillen *et al*., 1990; Fremion *et al*., 1999).

In *Drosophila*, two mutations have been identified as essential components of cAMP signaling, *dunce* (*dnc*) and *rutabaga* (*rut*), which encode cAMP phosphodiesterase and adenylate cyclase, respectively (Chen *et al*., 1986; Davis and Davidson, 1986; Levin *et al*., 1992). Both *dnc* and *rut* pupal hearts responded normally to an increasing temperature paradigm (Dowse *et al*., 1995). These mutants also have wild-type responses to cardioacceleratory transmitters (Johnson *et al*., 2002). These results, together with the demonstrated lack of effect with applications of forskolin, imply that the cAMP signaling system is either not involved in or plays a minor role in cardiac signaling (Johnson *et al*., 2002). However, the possibility remains that both *dnc* and *rut* gene expression is limited to other tissues, and other cyclases and phosphodiesterases are expressed in the heart. Consonant with this alternative, injection of a cAMP analog increases heart rate, producing modest but significant differences in heart rate (Johnson *et al*., 2002).

In *Drosophila*, injections of a cGMP analog significantly increase heart rate in a dose-dependent fashion suggesting a role for cGMP signaling in cardiac modulation (Johnson *et al*., 2002). cGMP modulation has been demonstrated as a cardiac mediator in the heart of *M. sexta* as evinced by experiments dealing with the cardioacceleratory neuropeptide, CAP_{2B}. This peptide liberates cGMP, which subsequently elevates the concentrations of free calcium (Tublitz, 1988; Tublitz *et al*., 1992; Davies *et al*., 1995). Further demonstration of the role that this cyclic nucleotide plays a role in cardiac modulation stems from experiments on a mutant of cGMP-dependent protein kinase (PKG). In *Drosophila*, multiple genes encode isoforms of PKG, and one was identified due to its effects on feeding behavior and called *foraging* (Osbourne *et al*., 1997). Two alleles occur in natural populations, *rover* and *sitter*, with *rover* alleles being wild-type and fully dominant (deBelle *et al*., 1989). The *sitter* allele is a hypomorph of *foraging*, producing less PKG, and these variants exhibit tachycardia (Johnson *et al*., 2002). While this result may not be in the predicted direction, it further implicates a cGMP-dependent pathway in modulating heartbeat. A possible explanation for the acceleration of heart rate in a hypomorph of PKG is that the targets of PKG are part of a feedback mechanism. The increase in intracellular calcium, caused by cGMP, might directly alter cardiac action potentials through the activation of the calcium-activated potassium channel, *slowpoke*. However, cGMP could be acting directly on other pacemaker ion channels like *eag*, as these channels are gated by this cyclic nucleotide (Bruggemann *et al*., 1993), or indirectly through the activation of PKG and its subsequent phosphorylation of target molecules. Therefore, the modulatory action of cGMP could occur at a number of different levels.

The release of intracellular calcium is a feature of pacemaker modulation, specifically of a calmodulin-CAM kinase II (CAMKII)-dependent signaling pathway. Flies bearing a single copy of *l(4)16*, which encodes CAM kinase II (Griffith *et al.*, 1993), eliminated the cardioacceleratory action of serotonin (Johnson *et al.*, 2002). Heart rate in these flies is stimulated by catecholamines, suggesting different mechanisms of action for these different agents. These genetic results were recapitulated by pharmacological experiments; a specific inhibitor of CAMKII abolished the cardioacceleratory effects of serotonin but not norepinephrine (Johnson *et al.*, 2002). The fact that ryanodine, which blocks the release of calcium from intracellular stores, nearly eliminates heartbeat (H. Dowse and E.C. Johnson, unpublished data), also argues that intracellular calcium is required for pacemaker function. The many peptide and transmitter receptors, which liberate calcium via a phospholipase C (PLC) dependent pathway, are indicative of a signaling role of intracellular calcium.

2.6.3.2.2. Small molecule transmitters The biogenic amines are common transmitters and hormones with multiple roles in different physiological, developmental, and behavioral processes. The wealth of classical genetic information and the advances in molecular genetic techniques in *Drosophila* have facilitated the identification of numerous transmitter and modulator substances and their respective downstream elements (Restifo and White, 1990; Buchner, 1991; Monastirioti, 1999). In *Drosophila*, biochemical analysis indicates the presence of the biogenic amines and acetylcholine (Watson *et al.*, 1993), and genes that encode critical enzymes for the synthesis of these transmitters have been identified, allowing for manipulations and assessment of biogenic amine signaling.

Injections of neurotransmitters have identified specific agents that are cardioactive. In *Drosophila*, pupal heart rate increases in response to application of serotonin, dopamine, octopamine, norepinephrine, and acetylcholine, in that order of potency (Johnson *et al.*, 1997). GABA modestly affects the heart of *Drosophila*, decreasing heart rate (Zornik *et al.*, 1999). Glutamate and glycine, common excitatory amino acid transmitters, are without effect on the *Drosophila* pacemaker (Johnson *et al.*, 1997; Zornik *et al.*, 1999). In *Periplaneta*, studies have demonstrated nearly the same pharmacological profile as in *Drosophila*, with serotonin being a powerful cardioacceleratory agent, followed in potency by octopamine, dopamine, and norepinephrine (Miller and Metcalf, 1968). Similar actions of these transmitters have been reported in *Manduca* (Prier *et al.*, 1994), and *Periplaneta* (Collins and Miller, 1977), suggesting conservation of cardiac aminergic signaling across insect orders.

2.6.3.2.3. Synthetic pathways The *pale* (*ple*) gene, which encodes the enzyme tyrosine hydroxylase (TH) (Neckameyer and White, 1993), catalyzes the rate-limiting conversion of tyrosine to L-dopa (Neckameyer and Quinn, 1989). This enzyme shows nearly 50% homology to vertebrate TH and is alternatively spliced to form two transcripts of 3.2 and 3.65 kb, with the latter being adult-specific (Neckameyer and White, 1993). Mutants in the *pale* gene are devoid of catecholamines, but not 5′-hydroxy-tryptamine (5-HT) (Budnik and White, 1987). A temperature-sensitive mutant, ple^3, significantly reduces heart rate and rhythms (E.C. Johnson and H. Dowse, unpublished data).

A major enzyme *en route* to dopamine and serotonin synthesis is dopa decarboxylase (Prosser and Brown, 1961; Tempel *et al.*, 1984). The *Drosophila* gene encoding the dopa decarboxylase (Ddc) enzyme (Hirsch and Davidson, 1981) is functionally similar to those of other species (Black and Smarelli, 1986). Raising temperature sensitive mutants for this gene at restrictive temperatures for 24–48 h causes the natural titers of these transmitters to fall to zero (Livingstone and Tempel, 1983). Heart rates and rhythms are also significantly decreased in Ddc^{ts1} mutants (Johnson *et al.*, 1997; Ashton *et al.*, 2001).

Another relevant enzyme that catalyzes the synthesis of octopamine is tyramine β-hydroxylase, which can be used as a marker for the identification of octopaminergic neurons. A null mutation in the tyramine β-hydroxylase gene results in an octopamine-less fly, but heartbeat has not been examined in this interesting genetic and physiological background (Monastirioti *et al.*, 1996). In an anatomical study using an antibody against this enzyme, a number of cardiac neurons in *Drosophila* were identified that are octopaminergic (Siegmund and Korge, 2001). Specifically, neurons arising from the *pars intercerebralis* that innervate the aortic wall are octopaminergic. These results not only indicate a cardioactive role for the biogenic amines, but also suggest a background role of neurotransmitters for normal pacemaker activity (Johnson *et al.*, 1997). This may also be the case in the cockroach, *Periplaneta*, in which the perfusion of hemolymph onto isolated hearts accelerates heart rate (Metcalf *et al.*, 1964). It is plausible that the decrement in heart rate exhibited by *Ddc* and *ple* mutants is caused by the loss of excitatory transmitters so that the effects

of inhibitory transmitters, unchanged by these mutations, are visible. Therefore, the relative levels of excitatory and inhibitory transmitters contribute to determining basal heart rate. Ashton *et al.* (2001) screened for aberrant cardiac phenotypes resulting from haploinsufficiency and found a number of loci exhibiting tachycardia and bradycardia. These loci included genes encoding receptors for serotonin as well as dopamine.

2.6.3.2.4. Transmitter receptors Small molecule transmitters can bind to multiple classes of receptor proteins, namely, G protein-coupled receptors (GPCRS: see **Chapter 5.5**) and ionotropic receptors. The annotated genome of *Drosophila* has identified the complement of proteins belonging to the GPCR superfamily (Adams *et al.*, 2000; Brody and Cravchik, 2000). A genomic analysis indicates the presence of multiple subtypes of receptors for each transmitter (Brody and Cravchik, 2000; Blenau and Baumann, 2001). Specifically, there are ~21 genes predicted to encode GPCRs for the biogenic amines (Brody and Cravchik, 2000), with multiple types for serotonin (Tierney, 2001), dopamine (Hearn *et al.*, 2002; Kim *et al.*, 2003), octopamine (Reale *et al.*, 1997; Chatwin *et al.*, 2003), tyramine (Saudou *et al.*, 1990) and acetylcholine (Harrison *et al.*, 1995), in addition to ~10 orphans that are phylogenetically similar to other amine receptors. Likewise, the presence of ligand gated ion channels have been identified in *Drosophila*, and function as receptors for histamine (Zheng *et al.*, 2002), GABA (ffrench-Constant *et al.*, 1992; **Chapter 5.4**), glutamate (Ultsch *et al.*, 1992), and acetylcholine (Chamaon *et al.*, 2002). However, precise definition of the ligands and the distribution of these receptors is presently lacking. Currently, the identification and characterization of all of these receptor(s) involved in cardioregulation is pending.

Despite these obstacles, the results from a pharmacological study in *Drosophila* can be applied to identify candidate receptors. Injections of serotonergic receptor agonists and antagonists suggest that a receptor with similar pharmacological properties similar to the mammalian 5-HT_2 receptor is involved in cardiac signaling (Johnson *et al.*, 2002). Such a receptor has been cloned in *Drosophila*, shares pharmacological similarities and interacts with the same downstream effectors to the homologous mammalian 5-HT_{2A}, 5-HT_{2B}, and 5-HT_{2C} receptors (Colas *et al.*, 1995).

2.6.3.2.5. Cardiac innervation A question to consider with studies on cardiomodulatory substances is upon what tissue is a given molecule exerting its affect? It is generally accepted that the origin of heartbeat in insects is myogenic and subject to neuronal modulation. For instance, some insects display heartbeat reversal, in which the "normal" posterograde conduction of beat is replaced by an anterograde mode of heartbeat (see above). This reversal of heartbeat mode is under neural control, and in the lepidopteran, *Agrius convolvuli,* it was found that the transmitter octopamine accelerated heartbeat in the anterograde heartbeat, and facilitated the reversal of posterograde to anterograde beat (Matsushita *et al.*, 2002). In *Manduca*, cyclical patterns of heartbeat mode are observed during metamorphosis, and, as TTX disrupts this physiological cycle, heartbeat reversal is under neuronal control (Dulcis *et al.*, 2001). Furthermore, systematic dissection of nerves resulted in the location of a precise nerve (DN8) that innervates the caudal end of the heart, and is responsible for this heartbeat reversal behavior (Dulcis *et al.*, 2001).

The site of action must be determined for cardiac transmitters, as information regarding anatomical targets for cardiac modulators is necessary to establish a complete picture of pacemaker modulation. In the cockroach, denervation of the heart abolishes the cardioactivity of acetylcholine, while other transmitters, including serotonin, were still effective (Metcalf *et al.*, 1964). The conclusion from these observations is that transmitters like serotonin are active on the heart proper, whereas acetylcholine is active at neuronal targets. A similar situation is present in *Drosophila*, in which a sodium channel mutation was used to assess likely anatomical sites of actions of cardioactive transmitters. When various transmitters were injected into the *para* mutant above the restrictive temperature, which eliminates neuronal signaling, the cardioacceleratory action of acetylcholine was found to be abolished (see above), while other transmitters including serotonin remained active (Johnson *et al.*, 2002). These results were similar to those obtained with coinjections of TTX with candidate transmitters (Johnson *et al.*, 2002). The above results, of course, do not preclude neuronal targets of serotonin, dopamine, octopamine, and norepinephrine, but imply that these transmitters are acting on the myocardium directly.

There is a fair amount of variability in innervation patterns in insects, which range from extensive, as exemplified in *Periplaneta*, to absent as in *Hyalophora* (Sanger and McCann, 1968a, 1968b; for relevant reviews see **Chapters 1.10**, **2.3**, and **2.4**). Perhaps, this variation in degree of innervation underlies differing identities and actions of peptide transmitters. Typically, most insects have a variable number of paired segmental nerves that innervate the heart, and these arise from

the ventral nerve cord. Some insects, most conspicuously the cockroaches, contain a pair of lateral heart nerves, which also emanate from the ventral nerve cord. Additionally, there may be nerves that innervate the anterior and posterior portions of the dorsal vessel and aorta (Siegmund and Korge, 2001). An interesting finding is that cardiac innervation differs as a function of development. In *Manduca,* cardiac innervation is absent in larval forms, but is present in the adult (Davis *et al.*, 2001). The same applies to *Drosophila*, where there are many ultrastructural differences between pupal and adult hearts (Curtis *et al.*, 1999), including the innervation of the adult heart (Dulcis and Levine, 2003).

2.6.3.2.6. Peptide transmitters and receptors Modulation of cellular activity by peptides has long been recognized in common signaling pathways as these transmitters can alter gene expression, enzymatic reactions, and electrical activity in target tissues. The large number of peptides reported to affect heartbeat in insects begs two questions. Are these effects specifically targeted to the heart? Is there a peptide or peptides dedicated as modulators of heart rate? It is possible that the cardioacceleratory effect of any given peptide is a mechanism to ensure its own circulation. Therefore, these effects may not be in specific response to a change in metabolic demand or to fulfill a functional physiological requirement, but rather a secondary effect to circulate a signal. Although this is an attractive hypothesis, it cannot be applied to inhibitory factors. Nonetheless, there is a clear need to modulate heartbeat in insects, and while a single, well-defined control system may not emerge, it is hard to deny the importance of peptide transmitters in cardiac regulation.

Small peptide hormones almost exclusively bind to GPCRs, and the complete annotation of the genomes of *Drosophila* (Adams *et al.*, 2000) and *Anopheles* has facilitated a detailed analysis of GPCRs (Holt *et al.*, 2002; Brody and Cravchik, 2000; Hewes and Taghert, 2001; Hill *et al.*, 2002). Therefore, identification of candidate receptors for cardioactive peptides will advance our knowledge of insect cardioregulation, and make it possible to pinpoint precise anatomical loci of peptide actions as well as to identify intracellular signaling components and to link these to altered heart function.

2.6.3.2.6.1. Crustacean cardioactive peptide Perhaps the best candidate for a dedicated regulator of heart function (if one exists) is the aptly named crustacean cardioactive peptide (CCAP), which was first isolated from the pericardial organs of the crab (Stangier *et al.*, 1988). Subsequent to its discovery, it has been isolated in a number of insect species, including *Locusta migratoria* (Truman *et al.*, 1996), *M. sexta* (Cheung *et al.*, 1992; Lehman *et al.*, 1993), and *T. molitor* (Furuya *et al.*, 1993). Remarkably, the primary sequence of this neuropeptide is invariant over large phylogenetic distances, and genes encoding this peptide have been identified in *Drosophila*, *Anopheles,* and *Manduca* (Hewes and Taghert, 2001; Loi *et al.*, 2001; Riehle *et al.*, 2002).

CCAP is a multifunctional transmitter and has different physiological roles; it has been implicated in the ecdysis behavioral program (Truman *et al.*, 1996; Baker *et al.*, 1999; Gammie and Truman, 1999; Park *et al.*, 2003), and the release of adipokinetic hormone (AKH) (Veelaert *et al.*, 1997; Harthoorn *et al.*, 2002), in addition to its established role as a myotropic and cardioactive agent. Ablation of CCAP-expressing neurons in *Drosophila* leads to deficits in the circadian rhythms of eclosion (see **Chapters 3.11** and **4.11**) as well as defects in the ecdysis program (Park *et al.*, 2003; **Chapter 3.1**). The role in ecdysis is of particular interest as it has been proposed that the mechanical forces required for cuticular shedding (see **Chapters 3.1**, **4.2–4.4**) and wing inflation derive from hemostatic pressure originating from heart activity (Park *et al.*, 2003). The targeted ablation of CCAP neurons in *Drosophila* leads to several phenotypes that may be explained by the loss of cardiac regulation. These animals displayed lengthened larval molts and increased mortality at the pupal stages, and animals surviving to adulthood have a characteristic phenotype of uninflated wings (Park *et al.*, 2003). Consistent with the notion of cardioactivity being an integral component of ecdysis, other factors involved in the ecdysis developmental program (see **Chapter 3.1**), namely ecdysis triggering hormone (ETH) (Park *et al.*, 1999) and eclosion hormone (EH) (Horodyski *et al.*, 1989), also increase heart rate (Baker *et al.*, 1999). The release of AKH via CCAP action may also be relevant in pacemaker activity. This peptide is involved in the mobilization of stored energy reserves from the fat body, and in a variety of insects, this peptide has cardioacceleratory effects. Perhaps, the cardioacceleratory effects of CCAP emanate from the action of other peptides, including ETH, EH, or AKH.

Consonant with its various actions in different insects, the anatomical distribution of CCAP varies from species to species. It is found in the central nervous system (CNS), in neuroendocrine cells, and in the *corpora cardiaca*, suggesting dual roles as both

a synaptic and hormonal modulator as follows. CCAP has been localized in several cardiac nerves in *Manduca,* which innervate the aorta, the alary musculature, and the caudal end of the adult heart (Davis *et al*., 2001). Likewise, in *Drosophila*, a number of cardiac innervating neurons express this peptide (Dulcis and Levine, 2003). The observation that this neuropeptide is cardioactive in *Drosophila* (Nichols *et al*., 1999b) at developmental stages that lack cardiac innervation suggests that the action of CCAP is direct on the pacemaker and/or the myocardium itself. Additionally, the neurons innervating the adult heart are labeled with antisera derived against CCAP, and suggest potential direct effects (Dulcis and Levine, 2003). Experiments on the neuronal control of heartbeat reversal in *Manduca* also support a direct action of this peptide, as CCAP accelerates heartbeat independently of mode (anterograde or retrograde) of heartbeat (Dulcis *et al*., 2001).

Recently, a GPCR sharing sequence similarity with the mammalian vasopressin receptors (Hewes and Taghert, 2001) was shown to respond specifically to this neuropeptide (Park *et al*., 2002; Cazzamali *et al*., 2002). The receptor encoded by the *CG6111* gene signals through increases in intracellular calcium in a heterologous expression system (Park *et al*., 2002). If this finding is paralleled in native tissues, a reasonable assumption given the relatively few subtypes of *Drosophila* G proteins, it is tempting to link CCAP activity to the activation of *slo* channels in the pacemaker. Increased free calcium could shift the kinetics of the channel to pass more current, thereby repolarizing the pacemaker, a feature invoked as a critical component of accelerating pacemaker activity. Alternatively, rises in free calcium potentially could activate components of the PLC pathway leading to the stimulation of PKC, which could phosphorylate pacemaker-relevant channels. With the repertoire of molecular genetic techniques available in *Drosophila*, manipulations of this receptor *in vivo* should provide insights into the mechanisms of CCAP modulation of heartbeat.

2.6.3.2.6.2. FMRFamides and Myosuppressins The FMRFamide related peptides (FaRPs) are a group of extended N-terminal peptides with a similar C-terminus, which were first identified in mollusks and include the FMRFamides, myosuppressins, and sulfakinins (Nässel, 2002; Taghert and Veenstra, 2003). The *FMRF* (*CG2346*) gene encodes a large propeptide that undergoes posttranslational processing to yield active peptides; eight potential peptides are predicted from analysis of the amino acid sequence, based on consensus sites for proteolytic cleavage and amidation (Hewes *et al*., 1998). Dromyosuppressin (DMS), encoded by a separate gene, *CG6440* (Nichols, 1992), has the primary sequence of TDVDHFLRFamide and is the sole *Drosophila* member of the FLRFamide subfamily.

Several of the individual peptides produced from the processing of the FMRFamide gene are cardioactive in *Drosophila* and slow basal heart rate (Nichols *et al*., 1999a; Johnson *et al*., 2000). Similarly, DMS significantly lowers heart rate in *Drosophila* (Johnson *et al*., 2000), contrasting the effects this peptide has on the larval neuromuscular junction (NMJ) (Hewes *et al*., 1998). The peptide is present in the cardiac recurrent nerve in a related Dipteran (Richer *et al*., 2000) and is suggestive of receptor expression in the heart. Similarly, FLRFamide is cardioinhibitory in the locust (Schoofs *et al*., 1993) and its presence is widespread, and it is generally agreed that these are inhibitory peptides. However, the inhibitory effects of the FMRFamides in *Drosophila* are not a common feature of peptidergic regulation of the cardiac pacemaker, as these peptides are cardioacceleratory in a majority of insects. Lastly, the sulfakinins are also cardioactive, accelerating heart rate at subnanomolar concentrations in the cockroach *Periplaneta* (Predel *et al*., 1999), but reports of cardioactivity in other insects are presently lacking.

A number of GPCRs have been identified as candidate receptors for the FMRFamides and myosuppressins. The receptor encoded by *CG2114* displays greater sensitivity to the peptide emanating from the processing of the FMRFamide gene (Meeusen *et al*., 2002; Cazzamali and Grimmelkhjuzen, 2002). This receptor is putatively linked to Gq pathways, increasing intracellular calcium levels. Therefore, this receptor, if its actions are direct, would probably be involved in initiating a cardioacceleratory pathway (McGaw *et al*., 1995). However, a pair of linked receptor paralogs encoded by *CG8985* and *CG13803* show greater sensitivity to the DMS peptide, but are also activated by the FMRFamides in the nanomolar range (Egerod *et al*., 2003b; Johnson *et al*., 2003b). Likewise, the *CG2114* receptor does respond to DMS, but is more sensitive to the FMRFamides (Meeusen *et al*., 2002; Cazzamali and Grimmelkhjuzen, 2002). All three of these receptors are distantly related to the thyroptropin releasing hormone receptor family (Hewes and Taghert, 2001) and given that these receptors do respond to related peptides, the actions of any one peptide is problematic and studies aimed at determining receptor expression are required. Furthermore, the *CG8985*/*CG13803*-encoded receptor pair is apparently coupled to Gi proteins, as these peptides cause a significant decrease in the

forskolin-stimulated increase of cAMP levels (Johnson *et al*., 2003b) and these receptors presumably could produce antagonistic actions to the *CG2114*-encoded receptor. The receptors encoded by *CG6851* and *CG6887*, which are related to the mammalian CCK receptors (Hewes and Taghert, 2001), respond specifically to two of the three predicted sulfakinin peptides (Kubiak *et al*., 2002).

The degree of relatedness of these peptides and the demonstrated pharmacological overlap of the receptors makes it difficult to pinpoint a singular mode of action for these RFamides, and future studies with these putative receptors will be important for refining the roles of these peptides as cardiac modulators. Nevertheless, the physiological activity and anatomical evidence of these peptides argue for an important role in cardiac regulation.

2.6.3.2.6.3. Proctolin The pentapeptide proctolin (RYLPT) was the first insect peptide to be isolated on the basis of its potent stimulation of hindgut contractions in *Periplaneta* (Brown and Starratt, 1975). Consequently, its distribution and actions throughout many orders of insects have come under intense scrutiny. In addition to its potent effects on hindgut contractions, proctolin increases heart rate in several insects, including *Tenebrio*, *Periplaneta*, *Locusta*, and *Drosophila* (Anderson *et al*., 1988; Sliwowska *et al*., 2001). Proctolin also affects the accessory pulsatile organs of the cockroach (Hertel and Pass, 2002).

Second messenger activation and ligand binding demonstrates that the GPCR encoded by the gene *CG6986* responds specifically to proctolin (Johnson *et al*., 2003a, 2003b; Egerod *et al*., 2003a). Proctolin liberates intracellular calcium with subnanomolar sensitivity in heterologous cells in accord with reports of proctolin action *in vivo* (Wegener and Nässel, 2000; Johnson *et al*., 2003a). An antibody against a portion of the receptor was used to determine anatomical expression, which confirmed its action as a cardioactive peptide. The receptor is expressed in pericardial cells, in neurons innervating the anterior portion of the adult heart, and in neurons terminating at the anterior aorta in the larvae (Johnson *et al*., 2003a). Expression of the receptor in neurosecretory cells indicates a possible role as a hormonal modulator, perhaps regulating the release of other cardioactive factors (Johnson *et al*., 2003a). This lends credence to the report of an inhibitory action of proctolin in *Drosophila* (Zornik *et al*., 1999), which contradicts a previous study in *Drosophila* (Anderson *et al*., 1988). Possible explanations to reconcile these differences could be the presence of multiple proctolin receptors and/or differential sites of action. The strong proctolin receptor expression in pericardial cells is difficult to interpret with regard to cardiac physiology and could suggest secondary effects. Identification of a candidate proctolin receptor, irrespective of species, will facilitate the cloning and characterization of proctolin receptors from other insects, like *Periplaneta* and *Locusta*. This will be invaluable considering the abundance of physiological studies on proctolin activity in these insects to address phlyogenetic differences in proctolin activity and potential for multiple receptors. Proctolin cardioactivity appears not to be a uniform feature in insects, as the peptide has no effect in *Anopheles* (Messer and Brown, 1995), and a receptor ortholog is absent (Johnson *et al*., 2003a).

2.6.3.2.6.4. The kinins The pyrokinins are a group of peptides that are characterized by their FXPRLamide sequences at the C-terminus. CAP_{2B}, a cardioacceleratory peptide has been isolated in *Manduca* (Huesmann *et al*., 1995) and *Drosophila* (Davies *et al*., 1995). In *Manduca*, this peptide is cardioacceleratory (Tublitz, 1988) and acts synergistically with the biogenic amines, namely serotonin and octopamine (Prier *et al*., 1994). Additionally, this peptide factor is associated with increased heart rates during flight in *Manduca* (Tublitz, 1989). In *Drosophila*, the peptide affects diuresis in the Malphigian tubules, and no cardiac actions have been reported. In *Drosophila*, a GPCR specific for this peptide has been isolated (Park *et al*., 2002). The *CG14575* gene encodes a GPCR related to the neurotensin ancestral group (Hewes and Taghert, 2001), and is activated by submicromolar concentrations of the peptide (Iversen *et al*., 2002; Park *et al*., 2002). This receptor is linked to increases in free calcium as demonstrated *in vitro* (Park *et al*., 2002), consistent with the actions of this peptide described *in vivo* (Tublitz, 1988; Davies *et al*., 1995). Other pyrokinin peptides in *Drosophila,* which are encoded by the *hugin* gene, are cardioacceleratory (Meng *et al*., 2002), and these peptides bind to the receptor paralogs, encoded by *CG8784* and *CG8795* (Park *et al*., 2002).

The tachykinins are a family of neuropeptides that are identified by a FXGXR at the C-terminal sequence. The tachykinins are multifunctional peptides with effects on the heart (Sliwowska *et al*., 2001) and other visceral muscles in a variety of insects (Nässel, 2002). Several peptides are produced from a tachykinin precursor and have similar EC_{50} values as determined by hindgut contractions (Siviter *et al*., 2000). Receptors have been identified that recognize these peptides: *CG6515* and *CG7887*

(Li *et al.*, 1991; Monnier *et al.*, 1995; Torfs *et al.*, 2001; Johnson *et al.*, 2003b). The *CG7887* receptor couples to multiple signaling pathways, and receptor orthologs have been identified in another dipteran, the stable fly (Torfs *et al.*, 2001).

The leucokinins are unrelated groups of peptides with pronounced effects on the fluid secretion by the stellate cells of Malpighian tubules (Coast, 1996, 2001; **Chapter 2.8**). There are limited reports on this peptide as a potential cardioactive agent, and they include anatomical evidence that this peptide is present in the lateral heart nerves in the cockroach *Leucophaea* (Winther *et al.*, 1996). In three different dipterans, including *Drosophila*, leucokinin immunoreactivity is present in transverse cardiac neurons (Cantera and Nässel, 1992). A receptor for this peptide was first identified in the snail *Lymnaea* (Cox *et al.*, 1997), and the *Drosophila* ortholog, *CG10626*, is a functional leucokinin receptor (Radford *et al.*, 2002).

2.6.3.2.6.5. Allatostatins and allatotropins The allatostatins are a group of unrelated peptides that inhibit the production and release of juvenile hormone from the *corpora allata* (see **Chapter 3.7**). Three different families of allatostatins have been isolated from different species: the allatostatin A family (Ast-A), characterized by a C-terminal sequence of FXFGLamide), isolated from the cockroach, *Diploptera* (Woodhead *et al.*, 1989, Pratt *et al.*, 1991); the allatostatin B family (with a diagnostic C-terminal GW-amide sequence), isolated from the cricket *Gryllus* (Lorenz *et al.*, 1995), and allatostatin C, isolated from *Manduca* (Kramer *et al.*, 1991). To date, only a single member of this peptide family has been identified in *Manduca* and *Drosophila* (Price *et al.*, 2002). These peptides differ in their allatostatic properties, and in their presence in different insects. For instance, all three types have been identified in *Drosophila* (Williamson *et al.*, 2001a, 2001b), although none appear to be truly allatostatic in these dipterans (Price *et al.*, 2002).

Allatostatin A inhibits heart rate in the cockroach *Blatella* (Vilaplana *et al.*, 1999) and this result is strengthened by immunological evidence that the cardiac lateral nerves in another cockroach, *Periplaneta*, express this peptide (Ude and Agricola, 1995). These cardiac nerves are absent in other insect orders, notably Diptera and Lepidoptera (Sanger and McCann, 1968a, 1968b; Davis *et al.*, 2001), and the potential cardiac activity of these peptides in these insects has not been reported, despite their presence (Hewes and Taghert, 2001; Vanden Broek, 2001). An interesting feature is the colocalization of Ast-A and FMRF immunoreactivity (Ude and Agricola, 1995). Whether this suggests redundancy or integration of these peptides as cardiac factors will require additional studies.

A similar scenario emerges with the cricket-like allatostatins (allatostatin B or myoinhibitory peptide, MIP). Immunoreactivity suggests the presence of the peptide in nerves innervating the locust heart (Schoofs *et al.*, 1996), although there is a dearth of corresponding physiological studies with this peptide providing additional evidence of cardioactivity. In *Manduca*, there is a colocalization of this peptide with CCAP (Davis *et al.*, 2003), and it is unknown if this suggests a role of this peptide in ecdysis and/or heartbeat. This peptide is released by the epiproctodeal gland in *Manduca* (Davis *et al.*, 2003), suggesting a hormonal function. Whether this peptide is a *bona fide* regulator of heartbeat and whether cardiac regulation by Ast-B is a widespread insect phenomenon remains to be seen.

The *Manduca*-like allatostatin, allatostatin C, is cardioactive in *Drosophila*, where application of this peptide inhibits heart rate (Price *et al.*, 2002). The activity of this peptide is presumed to be hormonal in nature; antisera to this peptide recognize numerous endocrine cells in the *Drosophila* adult midgut. It remains to be seen if this peptide is a cardiac modulator in other insect species.

Notably, GPCRs for each of these peptides have been identified in *Drosophila*: *CG2872* and *CG10001* respond to Ast-A (Birgul *et al.*, 1999; Larsen *et al.*, 2001; Lenz *et al.*, 2001); *CG14484* responds to Ast-B (Johnson *et al.*, 2003b); and *CG7285* and *CG13702* to Ast-C (Kreienkamp *et al.*, 2002; Johnson *et al.*, 2003b). The receptors for the Ast-A peptides belong to the galanin-like family of receptors, the Ast-B receptor belongs to the bombesin-like receptors, and the Ast-C receptors belong to the somatostatin-like receptors (Hewes and Taghert, 2001). With the exception of the Ast-A receptors, a few conclusions concerning these receptors and their subsequent mechanisms of cardioaction can be reached, as it is presently unknown through which second messenger systems these receptors are signaling and in what tissues they are found. The two Ast-A receptors, encoded by *CG2872* and *CG10001*, couple to Gi/o proteins in mammalian cells, as they were shown to signal through calcium in a pertussis-sensitive fashion (Larsen *et al.*, 2001). These results should serve as a hypothetical framework to address the *in vivo* action, signaling, and distribution of these various allatostatin receptors and their involvement in the cardiac system.

Allatotropin is a peptide that was first isolated in *Manduca* and mediates the release of JH from the

corpus allatum (Veenstra *et al.*, 1994; **Chapter 3.7**). It accelerates the heart rate in *Manduca* (Veenstra *et al.*, 1994), in another lepidopteran, the army worm, *Pseudaletia* (Koladich *et al.*, 2002), and in the cockroaches *Periplaneta* and *Leucophaea* (Rudwall *et al.*, 2000). A candidate gene encoding this peptide is conspicuously absent from the *Drosophila* genome (Nässel, 2002; Taghert and Veenstra, 2003), although antisera against this peptide labels various neurons (Zitnan *et al.*, 1993).

The distribution of this peptide, evaluated through immunocytochemistry, is in a number of cardiac relevant neurons, specifically in the cockroach lateral and transverse nerves. Additionally, this peptide is colocalized with serotonin in both the cockroach and army worm (Rudwall *et al.*, 2000; Koladich *et al.*, 2002), and there is evidence that these factors are acting synergistically on the army worm heart (Koladich *et al.*, 2002).

2.6.3.2.6.6. Corazonin and adipokinetic hormone (AKH) Corazonin was first isolated in the cockroach, *Periplaneta*, based on its potent cardioactivity (Veenstra, 1994). The peptide is widely distributed throughout many insect orders and is associated with a number of different behaviors. For instance, corazonin is implicated as the causative factor of the gregarious-associated pigmentation of cuticle in locusts (Tawfik *et al.*, 1999). Its functional role in *Drosophila* and many insects is unknown, and perhaps corazonin is a common cardioactive factor.

A GPCR (*CG10698*) for this peptide has been identified in *Drosophila* and activation of this receptor increases intracellular calcium levels (Park *et al.*, 2002; Johnson *et al.*, 2003b). The identification of a *Drosophila* corazonin receptor will determine if corazonin is involved in cardioregulation in *Drosophila* and/or whether it could be useful in identifying the cockroach ortholog for *CG10698*.

AKH is a neurohormone released by the *corpus cardiacum* to regulate hemolymph carbohydrate concentrations (review: Gade and Auerswald, 2003). Given its direct role in modulating mobilization of sugars, it is perhaps not surprising that it has been implicated as a cardioactive factor in *Drosophila* (Noyes *et al.*, 1995) as well as other insects. In *Drosophila*, a candidate GPCR, encoded by the *CG11325* gene, has been identified for this neuropeptide (Park *et al.*, 2002; Staubli *et al.*, 2002) and should help facilitate definition of cardiac relevant roles.

2.6.3.2.6.7. PACAP-like peptides The *amnesiac* mutation (Quinn *et al.*, 1979) affects learning and memory storage (Tully and Quinn, 1985) and ethanol sensitivity (Moore *et al.*, 1998), and produces a reduced heart rate and an associated cardiac arrhythmia (Johnson *et al.*, 1997). This gene has been cloned and found to encode the neuropeptide homologous to vertebrate pituitary adenylate cyclase activating peptide (PACAP) (Feany and Quinn, 1995), although the precise amino acid sequence of the peptide(s) remains unclear. This mutation also reduces oscillations of intracellular calcium in the *Drosophila* CNS (Rosay *et al.*, 2001). Further work is needed to map out the cardiac effects of this peptide.

2.6.3.2.7. Regulation of receptor activity If the effects of any transmitter are the consequence of its receptor(s) activation, then it also follows that factors that regulate receptor activity or expression may be critical in mediating or modulating cardiac effects. In mammals, GPCRs are downregulated by the concerted action of the arrestins and G protein-coupled receptor kinases (GRKs) (Kohout and Lefkowitz, 2003). Ligand binding places the receptor in a conformation that is recognized by GRKs and subsequently phosphorylated. This phosphorylation leads to the recruitment of cytoplasmic arrestins to the membrane, where GPCR–G protein interactions are blocked. The complex is then internalized, resulting in a reduction in the pool of receptors capable of being activated by ligand. GPCR regulation in insects is likely to be fundamentally similar to this, as one nonsensory arrestin (Roman *et al.*, 2000) and two GRKs (Cassill *et al.*, 1991) have been identified in the *Drosophila* genome. Additionally, *Drosophila* GPCRs have displayed similar properties in arrestin associations and these elements have led to the identification of several *Drosophila* GPCRs (Johnson *et al.*, 2003b). However, the impact that receptor regulation has on the cardiac system has not been evaluated fully. There is evidence to suggest that pacemaker function relies upon normal receptor regulation. In *Drosophila*, a mutation that disrupts receptor downregulation has profound effects on heartbeat; manifest as cardiac arrhythmia and the inability to respond normally to increasing temperature and cardioacceleratory transmitters (Johnson *et al.*, 2001). Electrocardiogram analysis of flies bearing the *shibire* (*shi*) mutation suggests that the cardiac pacemaker is being driven to rates that the myocardium cannot accommodate (Johnson *et al.*, 2001). The *shi* gene encodes dynamin (Chen *et al.*, 1991; Van der Bliek and Meyerowitz, 1991), which functions as a molecular motor (Shpetner and Vallee, 1992). Dynamin is essential for vesicle formation by forming a ring structure and excising clathrin coated pits (Hinshaw

and Schmid, 1995). Thus, dynamin is essential for receptor downregulation through the endocytotic machinery. This raises the possibility that the heart defects are caused by the loss of neurotransmitter receptor recycling due to impaired endocytosis in the pericardial cells or in the myocardium or both.

The *shi* phenotype is suppressed by another "regulatory" gene, *nap,* which is an allele of the *maleless* gene (Kernan *et al*., 1991). The *nap* mutation produces bradycardia and arrhythmia (Dowse *et al*., 1995). This gene encodes a RNA–DNA helicase and produces errors in the splicing of certain transcripts (Palladino *et al*., 2000; Reenan *et al*., 2000); therefore, the effects of this mutation are indirect. These results imply that the quantity of active channels and receptors represent a state variable of the cardiac oscillator.

2.6.3.2.8. Modulation of heartbeat by temperature One of the functional roles that heartbeat fulfills is that of thermoregulation, as initially described in the elegant studies of Heinrich on bumblebees. Clearly, poikilotherms must account for the wide range of environmental conditions. Heart rate is positively correlated with temperature and with increases across the physiological range (White *et al*., 1992). And while the observation that heartbeat is sensitive to temperature change is beyond dispute, the mechanisms that facilitate such changes are largely unresolved.

It could be that the physical chemistry of the system is responsible for altering heart rates with fluctuating temperatures. This hypothesis has some supporting experimental results; deuterium, which slows heartbeat, also decreases the temperature sensitivity of the system (White *et al*., 1992). However, work on the *nap* mutation has shown that this mutant is practically unresponsive over a wide range of temperatures (Dowse *et al*., 1995). These results would implicate that the magnitude of such change has to be mediated by a specific detection system. The pioneering work on cardiac function as a thermoregulatory mechanism by Heinrich also implicates a neuronal component of the modulation by temperature (Heinrich, 1970, 1976). However, flies carrying the *paralytic* mutation have normal heartbeat over a wide range of temperatures (18–42 °C) (Dowse *et al*., 1995) and given that this mutation disrupts neuronal function above 29 °C (Suzuki *et al*., 1971), this result suggests a lack of involvement of the nervous system.

The response to temperature in Ddc^{ts1} mutants is normal, suggesting that the mechanism by which temperature exerts its effects on heart rate is not mediated by an increase in neurotransmitter concentrations or efficacy (Johnson *et al*., 1997). Perhaps other transmitters are involved and are not perturbed in this mutant. To speculate wildly, the demonstration that Transient receptor protential (Trpc) channels can be gated by temperature could represent a direct mechanistic link of temperature modulation on the cardiac system.

2.6.4. Aging Heart

2.6.4.1. Insects as Models for Aging

2.6.4.1.1. Models of aging The process of growing old has fascinated biologists and natural philosophers for centuries. In recent years, genetic and biochemical studies using insect model organisms have begun to outline some of the mechanisms that underlie the aging process. Excitingly, and perhaps surprisingly, these mechanisms appear to be employed to control senescence in a broad spectrum of organisms, including yeast, nematodes, mice, and humans (Finch and Ruvkun, 2001; Partridge and Gems, 2002; Tatar *et al*., 2003). This section will briefly review recent work on the mechanisms of aging using insect models, then discuss some of the limitations of the insect model systems. Thus, it is concluded with a discussion of new techniques designed to address these limitations by making use of the insect heart as a model to identify factors that control aging at the level of an individual organ.

Two major hypotheses have been proposed to explain how organismal senescence occurs. The first, the "rate of living" hypothesis, as proposed by Daniel Pearl (Pearl, 1928), is that each individual has a genetically determined sum of vitality, and that each individual lifespan is controlled by the rate at which this sum of vitality is used up. The second, which we will refer to as the "genetic plan" hypothesis (Helfland and Rogina, 2003), asserts that changing patterns of gene expression over the lifespan of the animal leads to differential production of factors, including hormones, which tend to promote or prevent gradual deterioration of organ systems, until the eventual failure of at least one essential organ becomes the cause of mortality. Evidence from insect model systems has been used to support each of these ideas.

2.6.4.1.2. Oxidative stress The rate of living hypothesis can be explained molecularly by the "oxidative stress" hypothesis, which states that the underlying cause of senescence is accumulated damage caused by reactive oxygen species (ROS) to lipids, proteins, and DNA. ROS are generated as a byproduct of essential biochemical reactions during cellular respiration, but can accumulate to

damaging levels if produced more rapidly than antioxidant proteins, such as Cu,Zn-superoxide dismutase (SOD), and catalase can remove them. Thus, an organism with an increased activity level may be expected to accumulate higher ROS levels, thus accumulating more damage to cellular macromolecules and thereby undergoing an earlier senescence (Stadtman, 1992; Sohal, 2002).

By comparing the rates of mitochondrial ROS generation in dipteran species with widely varying lifespans, it has been observed that an inverse relationship exists between lifespan and rate of ROS generation (Sohal *et al*., 1995). In houseflies, lowering the rate of muscle activity (by preventing the animals from flying) leads both to a lower level of ROS accumulation in aging individuals and to a corresponding increase in lifespan (Agarwal and Sohal, 1994). Additional anecdotal evidence abounds in various insect species for an inverse relationship between metabolic rate and lifespan, e.g., worker honeybees that emerge in summer during the foraging season have shorter lifespans than worker bees that overwinter as nurses (Amdam and Omholt, 2002).

Conversely, when exposed to hyperoxic conditions, houseflies exhibit increased levels of ROS generation and protein modification, as well as a decreased lifespan (Sohal *et al*., 1993). Interestingly, the amount of oxygen consumption by houseflies during an average lifespan is the same under different metabolic conditions, while the rate of oxygen consumption varies inversely with the length of life (Miquel *et al*., 1976; Sohal, 1982).

Alternatively, attempts to increase the lifespan of fruit flies by overexpression of genes encoding antioxidant proteins have produced mixed results. Ubiquitous overexpression of Cu,Zn-SOD, Mn-SOD, catalase, or thioredoxin reductase gives no appreciable extension of lifespan, despite providing some degree of increased stress resistance (Seto *et al*., 1990; Reveillaud *et al*., 1991; Orr and Sohal, 1993; Mockett *et al*., 2003). Flies carrying an extra transgenic copy of Cu, Zn-SOD, and catalase, however, did live about one-third longer than controls (Orr and Sohal, 1994). More recently, inducible overexpression of Cu,Zn-SOD conferred a lifespan increase in some lines but not others (Sun and Tower, 1999), with the degree of lifespan extension being greatest in lines in which control flies had a relatively short lifespan. However, overexpression of the human Cu,Zn-SOD in fruit fly motor neurons is capable of extending lifespan by 41% (Parkes *et al*., 1998) and, remarkably, Cu,Zn-SOD overexpression in motoneurons can rescue the shortened lifespan of *Cu, Zn-SOD* mutants (Parkes *et al*., 1998). In summary, rate of production of ROS appears to have a powerful correlation with lifespan. However, overexpression of antioxidants seems to extend lifespan best in genetic backgrounds or tissues where antioxidant activity may already be low, while conferring little additional benefit to genetic backgrounds that are not already compromised for lifespan. This correlates well with studies showing little benefit to overexpression of oxidants in mice (Huang *et al*., 2000) or administration of antioxidants to mice or humans (Kohn, 1971; Kim *et al*., 1993; Albanes *et al*., 1995; Omenn *et al*., 1996).

2.6.3.1.3. Genetic programs of aging: insulin, juvenile hormone, and ecdysone Emerging evidence from insect models, especially the fruit fly *D. melanogaster*, supports the idea there may be one or several genetically regulated programs of aging that link the influences of metabolism, oxidative stress, and numerous signaling pathways. Compelling evidence for the existence of an intricate genetic control of aging comes from single gene mutations that cause an increase in lifespan. Examples include the putative G protein-coupled receptor *methusela* (*meth*) (Lin *et al*., 1998), the metabolite transporter *I'm not dead yet* (*Indy*) (Rogina *et al*., 2000), ecdysone receptor (*EcR*) (Simon *et al*., 2003), the insulin receptor substrate *chico* (*ch*) (Clancy *et al*., 2001), and certain alleles of the insulin receptor (*InR*) itself (Tatar *et al*., 2001).

While it is plausible that some, or even all, genetic mutations that affect lifespan may do so solely by affecting metabolic rates, there is a growing body of evidence suggesting that lifespan may be regulated by a programmed response to varying environmental conditions that involves release of neuropeptides, which themselves guide the release of hormones, and can regulate lifespan in a manner that can sometimes be separable from effects on fecundity or metabolic rate (Tatar *et al*., 2003).

A key hormone for regulation of aging in fruit flies (Tatar *et al*., 2003) is the sesquiterpenoid juvenile hormone (JH; see **Chapter 3.7**). Reduction in Insulin Receptor signaling by mutation in *InR* or *chico* leads to a drastic reduction in JH levels, while the extended lifespan conferred by such mutations can be rescued by treatment with the JH analog methoprene (Clancy *et al*., 2001; Tatar *et al*., 2001; Tu *et al*., 2002). Reduction in JH itself can also affect lifespan (Tatar and Yin, 2001).

The role of JH in the regulation of lifespan and fertility appears to be conserved for a variety of insects. For example, honeybee workers have varying levels of vitellogenin depending on whether they are short-lived summer bees or long-lived winter bees (Amdam and Omholt, 2002). Since JH

promotes vitellogenesis by regulating the production of vitellogenin in flies (Wyatt and Davey, 1996; see **Chapters 1.3** and **3.9**), these results may again reflect the importance of JH in lifespan regulation. The decision for a Monarch butterfly to be reproductively active or to be a longer lived migratory butterfly also appears to be regulated by JH titers (Herman, 1981; Tatar and Yin, 2001). Longevity can also be doubled in several species of grasshoppers by removal of the *corpora allata*, the site of JH synthesis. Suggestively, the longevity phenotype of animals undergoing such allatectomies is independent of the amount of muscle activity of the animals (Pener, 1972). Indeed, since the levels of JH production seem to influence diapause behavior in many insects, one could view the effects of reduced JH levels on the rate of aging as a less drastic version of diapause (Tatar and Yin, 2001).

Another line of evidence for genetically programed aging comes from microarray experiments, in which global gene regulation can be examined in genetically identical fruit flies of different ages. Such experiments have demonstrated that transcription profiles vary widely and reproducibly in fruit flies as a function of age as well as level of food intake (Pletcher *et al*., 2002). More targeted experiments using gene-specific reporter constructs or observing temporal changes in gene expression in particular tissues have also supported the idea that gene expression during aging is a dynamic, regulated process rather than a simple consequence of deterioration in global homeostasis (Rogina and Helfland 1995; Wheeler *et al*., 1995; Rogina *et al*., 1998; see also **Chapter 3.10**).

Additional recent evidence has suggested that perhaps the rate of living hypothesis and the genetic plan hypothesis are not necessarily in opposition. For example, fruit flies carrying mutations in the gene encoding the ecdysone receptor (*EcR*) have an increased lifespan, despite having normal fecundity (Simon *et al*., 2003). The ecdysone receptor is capable of forming a complex with ultraspiracle (Usp), which has been postulated as a receptor for JH (Xu *et al*., 2002). In turn, the EcR/Usp complex appears to interact with stress induced molecular chaperones as well as multiple histone deacetylases (HDACs) (Tsai *et al*., 1999; Arbeitmann and Hogness, 2000; **Chapter 3.5**), including Rpd3, mutations in which affect lifespan in both yeast and nematodes (Guarente and Kenyon, 2000). Interestingly, general chemical inhibition of HDACs in fruit flies can also result in increased lifespan with no apparent reduction in physical activity (Kang *et al*., 2002). Among the genes induced when HDAC activity is inhibited are those encoding superoxide dismutases, mitchondrial electron transport proteins, and molecular chaperones involved in stress response (Kang *et al*., 2002).

Thus, one can begin to sketch an interrelated chain of events (**Figure 10**), in which nutritional

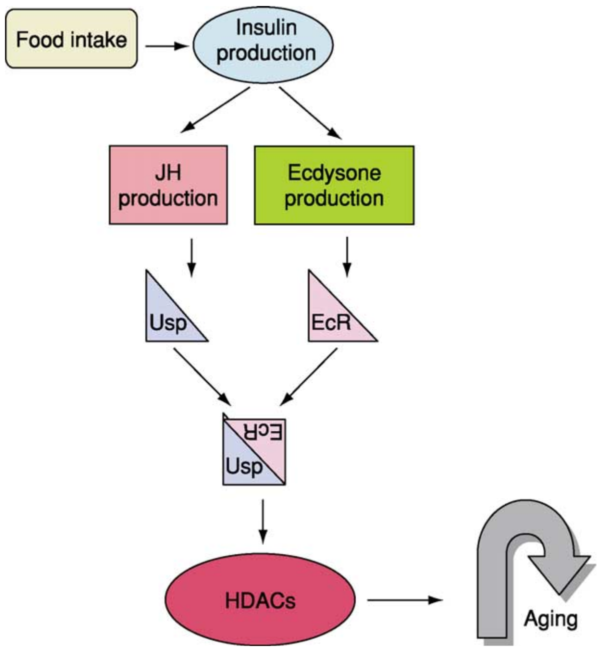

Figure 10 A cartoon depicting a simplified version of the events connecting food intake to the rate of aging. Food intake increases insulin signaling, which increases production of the secondary hormones ecdysone and juvenile hormone, which signal through their putative receptors, ecdysone receptor and ultraspiracle, respectively. These receptors are capable of heterodimerizing and regulating the activity of various histone deacetylases, which globally alter gene expression to drive the aging process.

and other environmental cues lead to the regulation of insulin production. This in turn leads to production of secondary hormones such as ecdysone and JH (see **Chapters 3.3** and **3.7**), which then induce transcriptional changes resulting in changes in gene activity necessary for stress response and defense against damage from ROS. Indeed, the damage produced by excess ROS itself seems to be nonrandom, preferentially targeting specific proteins for carbonylation (Yan *et al*., 1997; Yan and Sohal, 1998; Das *et al*., 2001), while leaving the vast majority of enzymes catalytically active throughout the aging process (Kanungo, 1980; Rothstein *et al*., 1980). This seems to be true not only in fruit fly mitochondria, but also in houseflies (Zahavi and Tahori, 1965; Yan and Sohal, 2000) and in rodent plasma (Jana *et al*., 2002).

As the above summary suggests, insect model systems have proven to be effective models for basic research into the mechanisms of aging. The fruit fly *D. melanogaster* has offered particular advantages (Helfland and Rogina, 2003) due to its quick reproductive cycle and nearly immediate reproductive capacity (justifying classification as adults for the purposes of aging research), the postmitotic nature of the majority of its tissues, and, most importantly, the many tools available for use in a widely studied genetic model organism.

2.6.4.2. The Insect Heart as a Model for Aging

2.6.4.2.1. Cardiac performance: towards a model for organ-specific aging A general shortcoming of any aging model thus far has been the lack of defining criteria during the aging process, such as stage-specific landmarks, before death. Thus, limitations still exist even to the utility of fruit flies in aging research. Despite the availability of large-scale genetic screens for mutations affecting aging, the complicated nature of lifespan as an output phenotype makes it difficult to reliably screen for mutations that reduce lifespan. As a result, the mutations identified in genetic screens to date have all been such as to extend lifespan (e.g., Lin *et al*., 1998; Rogina *et al*., 2000). Additionally, the long-term usage of the fruit fly as a laboratory animal has resulted in a selection process favoring high early life fecundity and short lifespan (Promislow and Tatar, 1998; Sgro and Partridge, 1999). As a result, some mutations that extend the lifespan of laboratory strains of fruit flies do not similarly extend the lifespan of fly strains with a greater inherent longevity (Sun and Tower, 1999; Leips and McKay, 2000; Rogina *et al*., 2000; Linnen *et al*., 2001; Spencer *et al*., 2003).

One way to combat these limitations would be to identify some sort of staged molecular or physiological clock, by which one could identify the stage of the aging process the animal was undergoing, independently of chronological time or lifespan. This has been attempted by taking advantage of age-specific gene expression profiles to mark the physiological “age” of individuals or cultured lines. In support of this idea, age-specific gene expression has been shown to vary proportionately in flies aged at different temperatures, where their “rate of living” is altered (Rogina and Helfland, 1995).

Another way to approach this issue would be to study “aging” of a specific organ system, and use the physiological deterioration of the tissue as a readout of the physiological age of the animal, irrespective of its metabolic rate or lifespan. Studies measuring the heart rate and cardiac performance under external electrical stress have strongly implicated the fly heart (dorsal vessel) as a useful readout in this context (**Figure 11**, Paternostro *et al*., 2001; Wessells and Bodmer, 2004). The heart performance has been observed to decline with age, and screens using heart performance at varying ages have identified loci that can regulate the rate of this decline (Wessells and Bodmer, 2004). Using this readout has allowed the isolation of mutants, which seemingly hasten the aging process, as suggested by the performance parameter changes, as well as mutants that retard this process. By testing cardiac performance at progressively older ages of various mutant lines, it has been observed that the correlation between lifespan and cardiac performance at advanced ages is strong. Interestingly, however, these parameters are separable in some cases (R.J. Wessells and R. Bodmer, unpublished data), suggesting that aging might not only be a global process, which affects the organism as a whole, but that individual organs may also be subjected to aging autonomously.

2.6.4.2.2. Mutations that affect cardiac performance with age In initial steps to characterizing the mechanisms of cardiac aging in the fruit fly, it has been observed that flies lacking Chico, an insulin receptor substrate, are not only long lived (Clancy *et al*., 2001; Tu *et al*., 2002) but also have slowed deterioration of cardiac performance, as measured both by resting heart rate and by the failure rate of hearts subjected to external electrical stress (R.J. Wessells, M. Tatar, and R. Bodmer, unpublished data). This slowed rate of cardiac deterioration is dependent on the reduction in JH levels that is a consequence of impairment of the insulin receptor signaling pathway (Tatar *et al*., 2001), since treatment of *chico* null flies with the JH analog methoprene restores normal lifespan. Similar results have also been obtained with certain

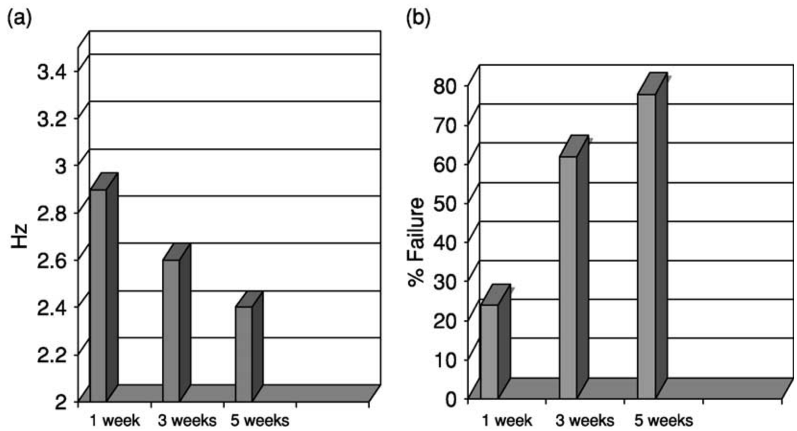

Figure 11 The *Drosophila* heart changes its physiological characteristics with age. (a) The decline in heart rate in flies between 1 and 5 weeks of age. (b) The increase with age of the percentage of flies exhibiting cardiac arrest or fibrillation (% failure) in response to electrical pacing (for methods see Wessells and Bodmer, 2004). Both parameters are consistent across several wild-type genotypes.

allelic combinations of the insulin receptor itself (R.J. Wessells, M. Tatar, and R. Bodmer, unpublished data).

The fact that cardiac performance at advanced ages can serve as an analytical readout for the effect of various mutations on aging at the organismal level, raises the question to what extent the cardiac aging process involves actual deterioration of the organ itself, and to what extent does the deterioration of cardiac performance simply reflect a gradual loss of metabolic homeostasis throughout the organism? Overexpression of the insulin receptor specifically in the heart leads to prematurely decreased cardiac performance in young flies as measured by response to external electrical pacing. Conversely, overexpression of inhibitors of the insulin receptor signaling leads to an improvement in cardiac performance in aged flies, suggesting that there is indeed an organ specific component to the aging process.

Another important question that can be addressed by examining cardiac performance at different stages of the lifecycle is the relationship of cardiac performance to lifespan. For example, when cardiac performance at advanced ages is improved by blocking insulin signaling in myocardial cells, the lifespan is not extended (R.J. Wessells, M. Tatar, and R. Bodmer, unpublished data). In contrast, mutations that cause a reduced heart rate throughout the life cycle result in a dramatically diminished lifespan (M. Fujioka, R.J. Wessells, R. Bodmer, and J.B. Jaynes, unpublished data). This supports a model in which gradual deterioration proceeds in all organs during aging, and failure of any organ system may lead to death. Interestingly, mutations that reduce heart rate do not necessarily result in diminished response to external electrical pacing, suggesting that stress response and resting heart performance are separable phenomena, both of which may contribute to lifespan.

Large-scale genetic screens are ongoing in multiple laboratories using age-dependent decline in cardiac performance to identify new loci that affect age related changes of the heart. It is expected that candidate genes will be identified that affect the global aging process as well as candidates that affect heart performance specifically. In addition to providing insight into cardiac physiology and aging in insect systems, such studies should produce many exciting therapeutic possibilities to be tested in mammalian systems. Such pioneering research in insects may eventually lead to new techniques for intervention to prevent or slow cardiac deterioration in the aging human population.

2.7 Tracheal System Development and Morphogenesis

A E Uv, University of Gothenburg, Gothenburg, Sweden
C Samakovlis, Stockholm University, Stockholm, Sweden

2.7.1. Introduction

Multicellular organisms have evolved specialized tubular organs to transport gases and liquids throughout the body. In vertebrates, such organs include the lung, the vascular system, and the kidney. Respiration in insects is mainly facilitated by an extensive tubular network, the trachea. A common feature of these tissues is their branched tubular structure, where epithelial cells are used as building-blocks. Morphogenesis of elaborate tubular networks has received much attention over the last decade, as it involves intriguing developmental questions: How do cells create tubes? How do new branches arise? What determines the direction of branch growth? How are the specific branch lengths and diameters determined? The respiratory organ of the fruit fly *Drosophila melanogaster* is an appreciated and thoroughly studied model organ for insect tracheal development and general branching morphogenesis. Here we aim to describe the main results from this research, which begins to highlight the basic molecular mechanisms leading to the development of a branched tubular organ.

The insect trachea is an air-filled network of tubes that spans the entire organism (**Figure 1a**). Air enters the network through specialized openings, called spiracles, and becomes distributed to all branches of the network, ending in narrow capillary-like blind-ended tubes, which facilitate gas exchange with target tissues. Tracheal tubes are void of contractile muscle cells, and simply consist of a single-layered epithelium with the apical cell surface facing the lumen. In order to optimize air supply, the tracheal branches must extend into all tissues in the animal, and individual tubes have to attain specific dimensions. This is achieved by a two-step developmental process: first, a stereotyped larval tracheal network forms during embryogenesis, controlled by a strict genetic branching program (**Figure 1b** and c). Later, during larval growth, the network expands by the enlargement of the preexisting branches and ramification of the blind-ended capillaries that infiltrate new targets to satisfy the metabolic demands.

During metamorphosis, the tracheal branches become reorganized, where most cells of the larval trachea are histolyzed and a new tracheal system is formed from imaginal tracheoblasts (Manning and Krasnow, 1993). As most information on tracheogenesis has come from studies of larval trachea

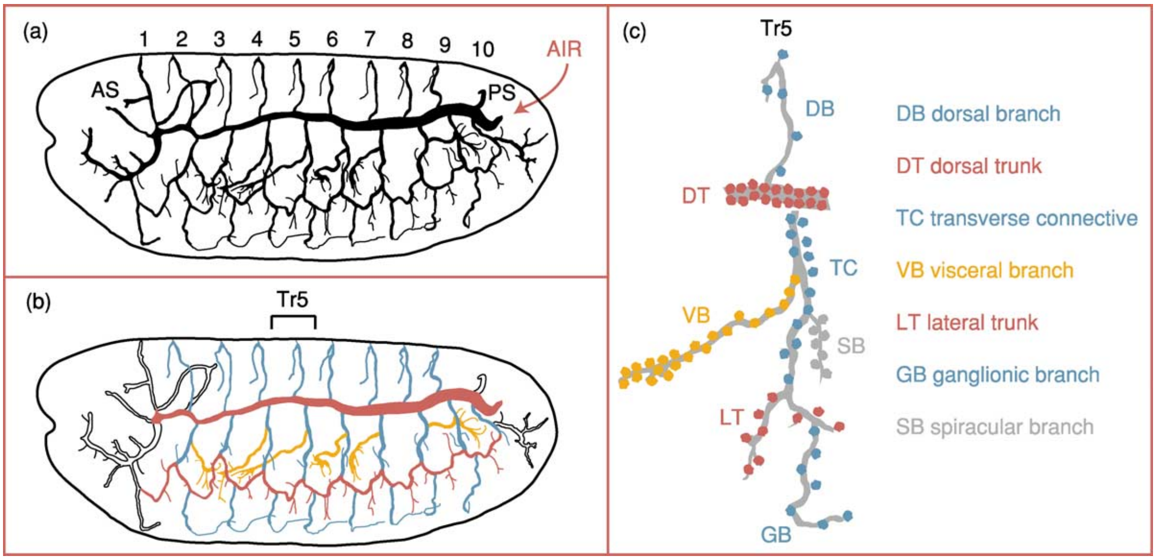

Figure 1 The *Drosophila* tracheal system. At late embryonic stage 16, the tracheal system is a fully branched network that will fulfill the respiratory demands of the newly hatched larvae. (a) Lateral view of the embryonic tracheal system (lumen) where dorsal is up and anterior is to the left. During larval life, air enters the posterior spiracles (PS) and becomes distributed to the gradually narrower branches, to reach the blind-ended capillaries for gas exchange with target tissues. The network is composed of 20 independently developed and fused tracheal metameres, 10 on each side the embryo (Tr1–Tr10), which are indicated by the numbers. (b) The main branches in Tr2–Tr9 are indicated by different colors of branch lumens. (c) The nomenclature for the main branches of a typical metamere (Tr5). Each metamere is composed of ~80 cells and displays a stereotyped branch patterning with characteristic numbers and positions of cells in each branch (circles represent nuclei, whose colors match those of the branch definitions in (b)). (Reproduced from Samakovlis, C., Manning, G., Steneberg, P., Hacohen, N., Cantera, R., *et al.*, **1996b**. Genetic control of epithelial tube fusion during *Drosophila* tracheal development. *Development 122*, 3531–3536.)

during embryogenesis, we focus our discussion on these aspects of tracheal development.

2.7.2. Histological Description of the Larval Tracheal System

The fully developed larval trachea consists of a continuous single-layered squamous epithelium of ~1600 cells, with the apical cell surface facing the lumen and the basal surface facing the internal tissues. The luminal surface is lined by a cuticle, which is secreted by the tracheocytes and is thought to function as a barrier against dehydration and invading microorganisms. Both the tracheal epithelium and its apical lining are continuous with the epidermis and the epidermal cuticle through the spiracular branches. A basal lamina surrounding the outer tube surface is also secreted, at least in part, by the tracheal cells.

Each tracheal cell is tightly connected to its neighboring cells, via intercellular junctions, along their lateral surfaces (Tepass and Hartenstein, 1994). The "zonula adherens" (apical junction) is located near the apical (luminal) surface, whereas pleated septate junctions are found at the lateral cell surface providing a diffusion barrier across the epithelium (**Figure 2**). Although gap junctions are only sporadically detected in the tracheal epithelium by electron microscopy (Tepass and Hartenstein,1994), recent experiments show that several gap junction proteins (innexins) are persistently expressed in the tracheal cells (Stebbings *et al.*, 2002).

How do epithelial cells create tubular structures? Studies of the larval trachea have revealed four different tubular designs, each of them associated with a distinct cellular architecture and a certain range in diameter and length (Samakovlis *et al.*, 1996a; Beitel and Krasnow, 2000) (**Figure 2**). Type I tubes (represented by the dorsal trunk) are composed of flattened, wedge-shaped cells connected by intercellular epithelial cell junctions. In a cross-section of the dorsal trunk, two to four cells encircle the lumen and provide a tube diameter of 4–5 μm. The second tube type (type II) is also multicellular, but narrower (~1 μm in diameter), and is represented by the dorsal, visceral, and ganglionic branches. Type II branches are formed by cells that are rolled up and sealed by autocellular junctions. Each tube-shaped cell is connected to its proximal and distal neighbors by intercellular junctions. Type III tubes are represented by the bicellular fusion-branches (anastomoses) that connect the individual metameres to a network. These tubes consist of a

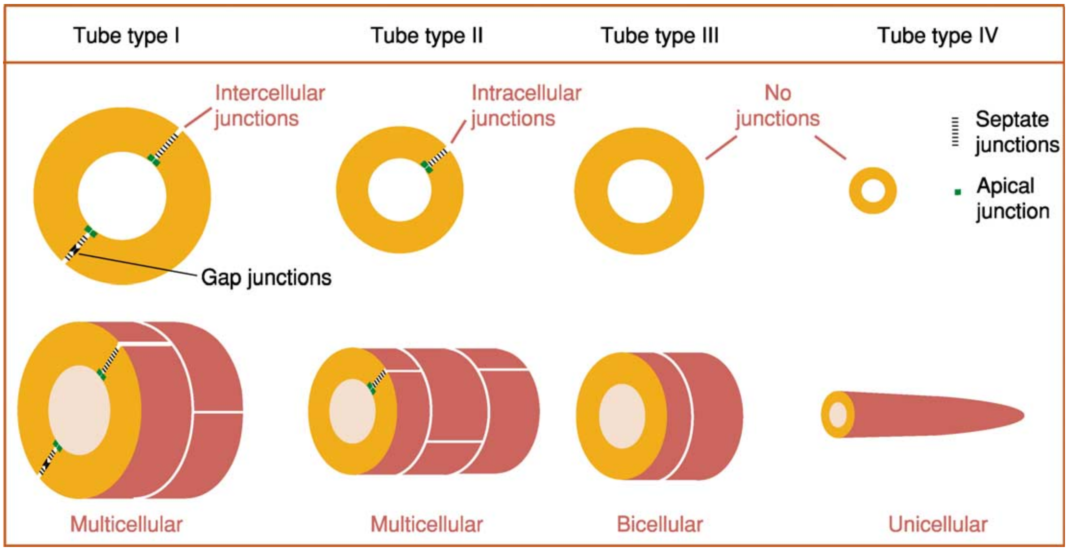

Figure 2 Cellular architecture of tracheal branches. Four structurally distinct tracheal tube types, termed I, II, III, and IV, have been described in the tracheal system. Top panels illustrate cross-sections of the different tube types, and their cellular architectures are drawn below. Type I: the main airways (4–5 μm diameter) are multicellular branches built from wedge-shaped cells surrounding the lumen circumference. Type II: air distribution to dorsal and ventral regions proceeds via narrower (∼1 μm) multicellular branches in which single tube-shaped cells with autocellular junctions encircle the lumen. The cells lie in a row and form intercellular junctions to proximal and distal cells within the branch. Type III: bicellular fusion branches (anastomoses) connect the individual metameres and are made by two cells. Each fusion cell is doughnut-shaped with no autocellular junctions and forms intercellular junctions with its fusion partner (and with the following cell in the primary branch). The type III lumen diameter is the same as that of the primary branches they connect, and varies between 0.5 and 5 μm. Type IV: terminal branches mediate gas exchange with target tissues and are made up of seamless (without autocellular junctions) tubular protrusions (<0.5 μm diameter) from single cells. Their large surface area and thin walls facilitate gas diffusion.

pair of doughnut-shaped cells, connected by intercellular junctions. In contrast to the cells of the narrow multicellular type II branches that fold over themselves, type III tubes are seamless, without intracellular junctions, and their diameter varies from 5 to 0.5 μm, depending on which of the primary branches they connect. Type IV tubes are represented by the blind-ended tracheoles. These branches are extended, hollow protrusions emanating from a single terminal cell, and become increasingly narrower along their length (less than 0.5 μm). A single terminal cell can form up to three capillaries during embryogenesis and many more during larval life, depending on the tissue to which it is attached to (see Section 2.7.3.3). For comparison to other tubular organs, the first tube type is found in lungs, blood vessels, and many glandular organs, whereas seamless tubes and tubes with autocellular junctions have been found in the vertebrate vasculature (Wolff and Bar, 1972) and the *Caenorhabditis elegans* excretory cell (Buechner, 2002).

2.7.3. Embryonic Tracheal Development: Morphogenetic Events

The metameric structure of the embryonic trachea (**Figure 1**) reflects its developmental origin, as it originates from 20 independent units with similar branching patterns, 10 on each side of the embryo (Samakovlis *et al*., 1996a). Each tracheal metameric unit (named Tr1–Tr10) is initially an epithelial pocket formed by invagination of epidermal cells during stage 10, and contains approximately 80 cells. The cells are oriented with their apical membrane lining the lumen and their basal cell surface facing the developing embryonic tissues. Over the next 12 h (until the end of embryogenesis) and without further cell division, the cells in each of these pockets undergo a synchronized program of branch outgrowth and branch fusion to generate a continuous tubular system (Samakovlis *et al*., 1996a). The branching process involves most aspects of epithelial morphogenesis, with extensive but highly regulated changes in cell shape and cell movements, and is divided into the following phases: invagination, primary branch formation, secondary branch formation, terminal branch formation, and branch fusion. Throughout these phases, the developing tracheal epithelium maintains its apical basal polarity and barrier function, and secretes luminal components. Just before larval hatching, the filamentous material filling the tubes during embryogenesis is cleared, and the tracheal system becomes functional as air fills the system and the posterior spiracles open up.

In this section, the different phases of embryonic tracheogenesis are discussed, focusing on tracheal branch morphology and the cellular events that underlie formation of the different branches. The different developmental stages are illustrated by tracheal luminal staining (**Figure 3**) and by green fluorescent protein fluorescence (**Figure 4**).

2.7.3.1. Invagination of Tracheal Precursor Cells

During stage 10, the 20 tracheal primordia can be recognized in the thoracic and abdominal segments T2–A8 as ectodermal placodes, 10 on each lateral side of the embryo (Campos-Ortega and Hartenstein, 1985). Each placode is a slightly thickened region of the epithelium with a shallow central depression, composed of tightly packed columnar cells. During stages 10 and early 11, the tracheal precursor cells undergo their 15th and 16th cell division cycles. Cell division cycle 15 occurs just before invagination, and cell cycle 16 occurs while the cells invaginate towards the underlying mesoderm to form the 20 tracheal pits. After the 16th cell division cycle, there are about 80 cells in each tracheal metamere 2 to 9 (Tr2–Tr9), and approximately 150 cells in Tr1 and 50 cells in Tr10. No further cell divisions are observed in the tracheal system until the onset of metamorphosis (Samakovlis *et al.*, 1996a).

As the tracheal precursor cells invaginate, the tracheal pits close but remain connected to the epidermis through the cells of the spiracular branch (SB). During stage 11, each pocket begins to form six buds, which will give rise to the primary branches. In the following sections, we are only discussing the events taking place in Tr2–Tr9. For a description of the first and tenth tracheal metameres, the reader is refered to a previous review (Manning and Krasnow, 1993).

2.7.3.2. Primary Branching

By mid stage 12, six primary branches have formed within each tracheal metamere. The six primary branches are termed dorsal trunk anterior (DTa), dorsal trunk posterior (DTp), dorsal branch (DB), visceral branch (VB), lateral trunk anterior (LTa), and lateral trunk posterior/ganglionic branch (LTp/GB) (**Figure 3**). Each branch appears as a finger-like extension, which grows away from the site of invagination in a stereotyped manner that is similar for all metameres. All primary branches start as type I tubes, and maintain their tubular structure and integrity as they grow. Their outgrowth is initiated by the extension of broad cellular protrusions from the tip cells in each bud. Subsequently, the cell nucleus moves in the same direction, and the apical surface enlarges to promote lumen extension. In this way, three branches grow out from the dorsal region of each pocket to form DTa, a short DTp and DB, one from the central region of the pit forming the VB, and two from the ventral region to form the LTa and LTp/GB. A few cells within the central region of the pit form the transverse connective (TC), which connects the dorsal and ventrolateral parts of the tracheal metamere. The spiracular branch (SB), which is constituted by cells that have remained near the site of invagination, closes during stage 12 (Campos-Ortega and Hartenstein, 1985), and the branch collapses. Thus, the SB has no respiratory function in the *Drosophila* larvae, but it opens at each molt to expel the tracheal cuticle.

The six primary branches continue their extension toward their targets throughout stages 12 and 13 (**Figure 3**). The DB grows towards the dorsal midline, following mesodermal grooves just underneath the epidermis. The DTa and DTp grow in the anterior and posterior directions, respectively, and traverse fields of mesodermal cells, following a groove as they migrate (Franch-Marro and Casanova, 2000). Visceral branches grow inwards to target the gut: VB2 (Tr2) grows towards the junction between foregut and midgut, VB4–VB7 (Tr4–Tr7) extend inwards and anteriorly along the lateral surface of the midgut, and VB8 (Tr8) bifurcates into an anterior and posterior branch on the surface of the gut (Tr3 and Tr9 do not form visceral branches). The LTa extends in the anteroventral direction towards the LTp of the preceding tracheal metamere, and the GB, which now can be discriminated from the LTp, grows ventrally towards the central nervous system (CNS).

During stages 14 and 15, three of the primary branches, DB, GB, and VB, continue to extend (**Figure 3**), developing into narrow type II primary branches. This conversion in the structure of the tubes involves substantial changes in cell contacts and shapes, and results in the repositioning of cells that initially face each other, into a single row around the lumen. The cellular rearrangements involved in the process have not yet been described in detail, but they resemble the intercalation of cells in epithelial sheets.

2.7.3.3. Secondary Branching

As primary branches navigate towards their targets, a distinct number of cells, typically located at the tip of each primary branch, sprout off and form smaller unicellular branches (Samakovlis *et al.*, 1996a). Approximately 23 sprouts emerge during stage 14 within each hemisegment. Twenty of these will grow towards target tissues and form terminal branches,

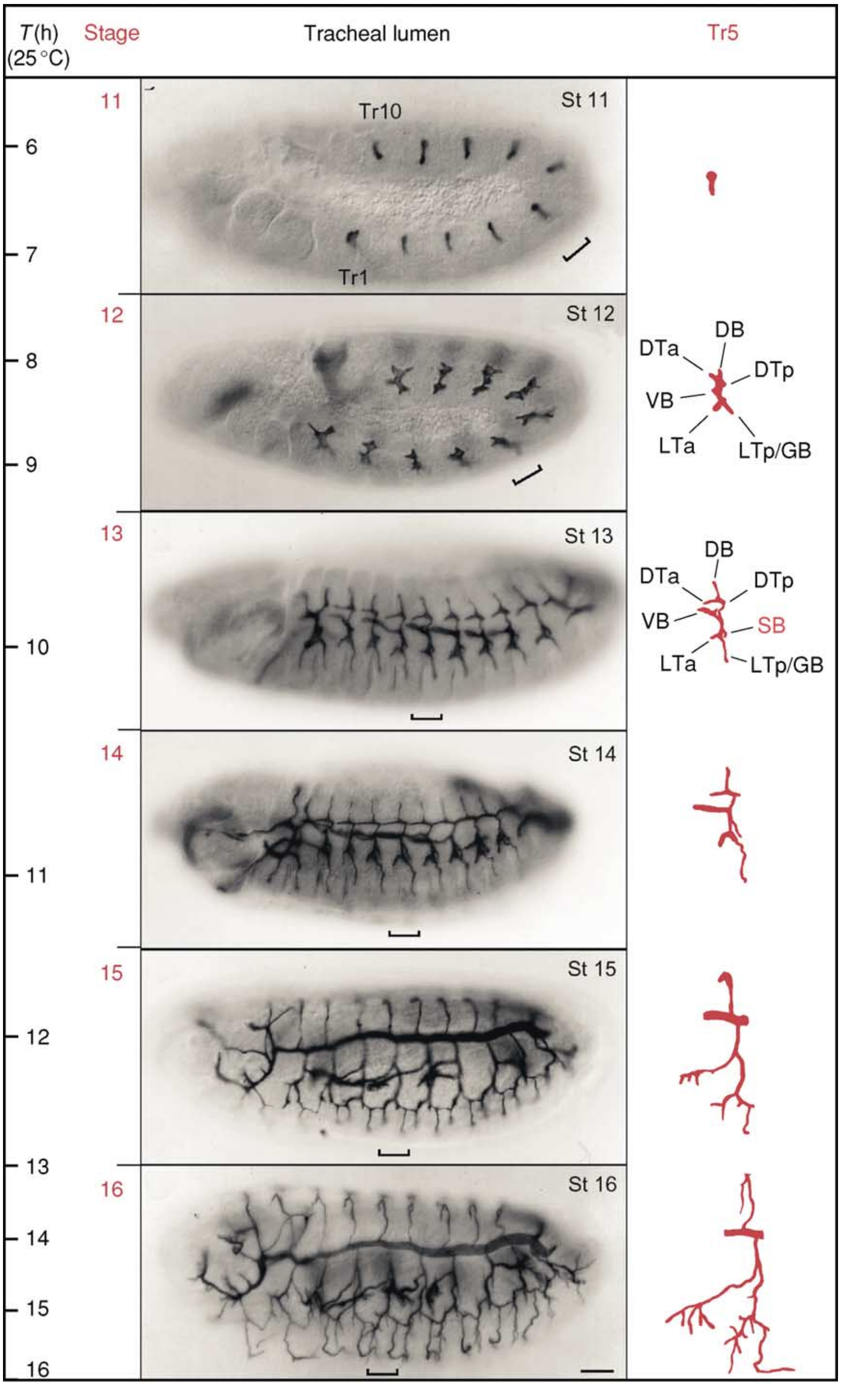

Figure 3 Overview of embryonic tracheal development. The left side of the tracheal system from stage 11 to stage 16, visualized by staining the lumen with the antiserum TL-1 (stages 11–14) and mAb2A12 (stages 15 and 16), is shown in the central panel, where dorsal is up and anterior is to the left. The age of each embryo can be deduced from the left axis in terms of hours after egg laying (AEL) at 25 °C. In the right panel, the lumen of a representative metamere (Tr5) for the relevant stage is drawn, and lines point to the six developing primary branches, as well as transverse connective (TC), which forms between the dorsal and lateral trunk. At stage 11, the lumina of Tr1 to Tr10 are seen as individual sacks, elongated in the dorsoventral orientation. These begin to bud, forming six rudimentary primary branches, which, during stage 12, become evident as protrusions that extend in distinct orientations. During stage 13, primary branches continue to grow, and the fusions between DTa and DTp begin. At stage 14, the dorsal trunk fusions are completed to form a continuous trunk, and the remaining primary branches ensue their elongation. During this stage, secondary branches also begin to sprout. At stage 15, the LTa and LTp have met and fused to form the lateral trunk, and the dorsal and ganglionc branches continue their extension toward the dorsal and ventral midline. The fusion events along the dorsal midline, to connect the left and right sides of the tracheal network, occur during stage 16. At the end of this stage, all fusion events are completed and terminal branches appear as long luminal protrusions from the primary branches. DB, dorsal branch; DTa, dorsal trunk anterior; DTp, dorsal trunk posterior; GB, ganglionic branch; LTa, Lateral trunk anterior; LTp, lateral trunk posterior; SB, spiracular branch; VB, visceral branch.

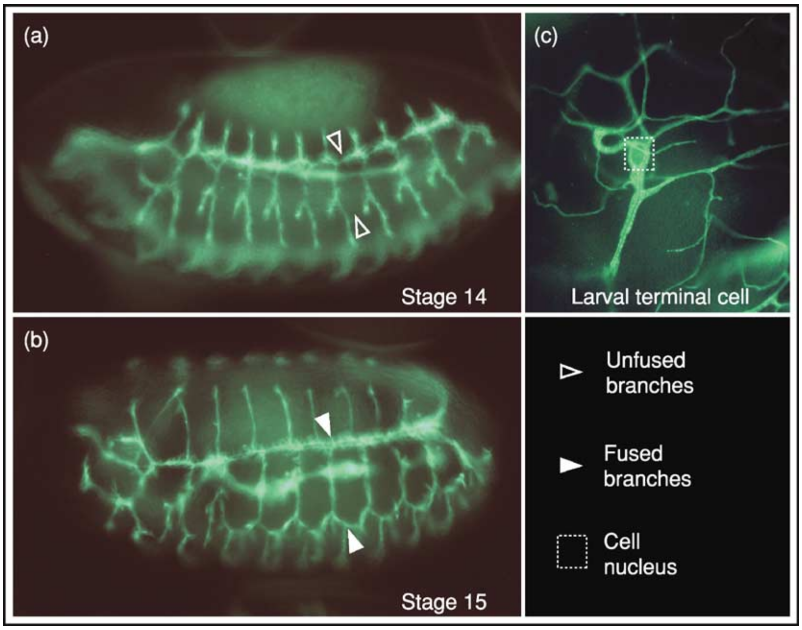

Figure 4 The tracheal system visualized by green fluorescent protein (GFP) fluorescence. GFP expressed in the developing trachea using the UAS-GAL4 system can be used to follow the cellular behavior during tracheal development, and visualization of the larval tracheal network. (a) and (b) A GFP reporter associated to microtubuli (Tau GFP) in the trachea of an early stage 14 embryo (a) when the dorsal trunk fusions are just initiated (upper open arrowhead) in a posterior to anterior gradient. The most posterior fusion event is already completed, but lateral trunk fusion events are not yet initiated (lower open arrowhead). (b) At stage 15, 2 h later, the dorsal and lateral trunk fusions are completed (filled arrowheads). Anterior is to the left, dorsal is up. (c) A single ramified terminal cell in a third instar larvae visualized by a cytoplasmic GFP marker. The nucleus is boxed, and the thin cellular extensions are type IV tubes that extend into surrounding tissues for gas exchange.

and three will contact corresponding sprouts from neighboring tracheal metameres to form branch fusion anastomoses. In addition, two fusion cells are located at the tip of the DTa and DTp, respectively, but these do not generate extended secondary branch sprouts. The position and number of unicellular sprouts within each primary branch is illustrated in Figure 5a.

The initial outgrowth of these branches has been termed secondary branching, but it is not entirely clear how these branches form and into which tube class they belong. In doublelabeling experiments, using antibodies against a cytoplasmic marker for tracheal cells and a septate junction protein, it appears that these branches are type II branches in their proximal region (i.e., the cell is folded over itself and sealed with autocellular junctions), but "seamless" type III tubes at their distal end (lacking autocellular junctions) (Samakovlis *et al.*, 1996b). More recent analysis of the roots of the new branches, however, indicates that the apparent autocellular junctions in the proximal region of the sprout actually belong to the adjacent stalk cell of the primary branch. This following cell in the stalk of the primary branch seems to penetrate the proximal end of the unicellular sprouts to provide an initial lumen, whereas the unicellular sprout itself forms a seamless tube that grows on top of the stalk cell lumen (Uv *et al.*, 2003). At the tips of DB, VB, and LTa, where two or more unicellular branches are followed by a single stalk cell, the stalk cell is predicted to form a bi- or trifurcated lumen to supply each unicellular sprout with a proximal lumen.

2.7.3.4. Branch Fusion

Branch fusion is a prerequisite for the function of many tubular networks. During mammalian angiogenesis, for example, newly sprouted capillaries fuse to each other or to preexisting vessels to facilitate blood circulation. In *Drosophila*, branch fusion connects the primary branches of the 20 independent hemisegments to a continuous network. Two cells, one at the tip of each connecting branch, undergo a complex process of partner recognition and intracellular tube formation to link adjacent branches by type III tubes (Samakovlis *et al.*, 1996b).

Within each hemisegment there are five fusion cells, one at the tip of each DTa, DTp, DB, LTa, and LTp (Figure 5a). During stage 13, the DTa and DTp from neighboring metameres meet endon and fuse to form the two dorsal trunks, one along each side of the embryo. The dorsal trunk fusion events

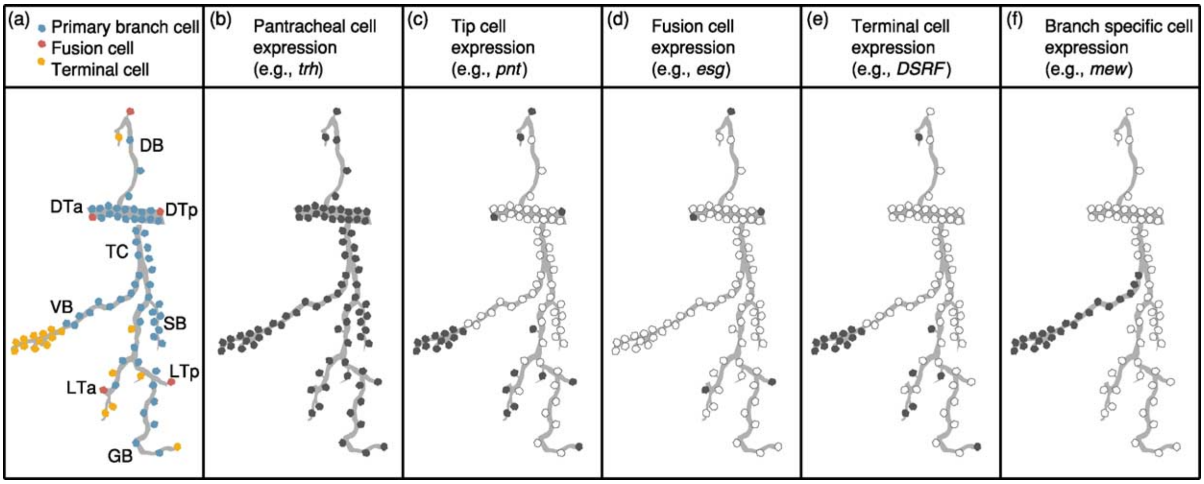

Figure 5 Distinct cell identities and gene expression patterns within each metamere. All drawings illustrate one typical tracheal metamere, lateral views with anterior to the left. (a) Multicellular primary branches of type I and II branches (blue nuclei) form the basic framework. Unicellular branches that sprout off from these form either terminal branches (type IV tubes, yellow nuclei) that target extratracheal tissues for oxygen delivery, or fusion branches (type III tubes, red nuclei) that connect the primary branches of neighboring metameres through luminal branch fusion. (b–f) Expression of different tracheal gene classes is indicated by filled nuclei. (b) Pan-tracheal genes, e.g., *trachealess*, are expressed in all tracheal cells. (c) Pantip genes, such as ''*pointed*,'' are expressed in the cells that form unicellular sprouts (fusion and terminal branches). (d) Fusion genes are specifically expressed in the five fusion cells; *escargot* is the earliest known fusion gene. (e) Terminal branch genes, such as *DSRF*, are expressed in all cells that will form terminal branches. (f) Expression of branch-specific genes is confined to the cells of one or a few branches, and *multiple edematous wings* (*mew*), encoding an αPS1 integrin, is an example that is specifically expressed in the visceral branch.

generally occur in a gradient across the embryo, with the posterior metameres fusing first (**Figure 4a** and **b**). Each of the dorsal trunk fusion cells migrates over a relatively short distance, before it meets its partner from the adjacent metamere to form a specialized connecting branch (type III tube) with the same diameter as the dorsal trunk.

The lateral trunk fusion events generate the continuous lateral trunk and are mediated by the fusion cell lying at the tip of LTa and a fusion cell that sprouts off LTp/GB in the preceding hemisegment. These anastomoses also form in a temporal sequence starting from the posterior metameres during stage 14, and ending in the most anterior ones during early stage 16. Finally, the fusion cells lying at the tip of each DB link the left and right sides of the trachea together at the dorsal midline, generating the 10 dorsal anastomoses. Occasionally, some DB branches are found unfused at hatching. In wild-type embryos, the number of unfused dorsal branches may vary between 0% and 5%. In addition, the GBs of Tr1, Tr2, and Tr3 form ventral anastomoses during stage 17 by connecting the three most anterior GBs with the GBs of the contralateral metameres.

Fusion branches are tubes with the same luminal diameter as the branches they connect, yet the strategy for generating such tubes must differ from that employed during primary branching, as fusion cells are doughnut-shaped and lack autocellular junctions. The fusion event begins as the fusion cells extend broad cytoplasmic processes towards each other. After the two fusion cells have recognized each other and established an initial contact point, they move closer to each other broadening their contact surface, and simultaneously forming a new lumen continuous with the primary branch lumen (Samakovlis *et al.*, 1996b). Lumen growth within the fusion cell appears to involve the assembly and fusion of luminal vesicles, thus producing a junctionless unicellular tube.

2.7.3.5. Terminal Branching

Most secondary sprouts do not form fusion anastomoses but instead develop into terminal branches (type IV). They extend away from primary branches to target distinct cells and tissues for gas exchange. These blind-ended capillaries are liquid-filled at the end and become closely associated with the plasma membranes of target cells to allow gas diffusion. Despite that terminal branches are generated from single cells, they may extend more than 50 μm during embryogenesis and undergo extensive ramification during larval life (**Figure 4c**) (Wigglesworth, 1983; Guillemin *et al.*, 1996; Samakovlis *et al.*, 1996a).

The initial sprouting of terminal cells in the interim of stage 14 (**Figure 3**) appears analogous to that of fusion cells. The cells extend broad cytoplasmic processes away from the primary branch, move their nuclei along, and acquire an initial branch lumen

that may be provided by the neighboring stalk in the primary branch. The succeeding terminal branch growth, which accounts for more than 90% of the embryonic branch length, is, however, an entirely intracellular process. It entails extension of long and narrow cytoplasmic protrusions that shortly afterwards become invaded by a lumen (Guillemin *et al*., 1996). Terminal branches are void of autocellular junctions, and their lumen apparently grows by fusion of luminal vacuoles in a proximal to distal orientation. During terminal branch extension, the terminal cell nucleus remains nearly in the same position. Thus, terminal branch growth may be reminiscent of the growth of neuronal axons, except that the cellular protrusions become hollow.

During embryogenesis, terminal branches follow prefixed paths towards a variety of targets, including the epidermis, different muscles, the digestive system, and the CNS, and may follow elaborate routes to reach their targets. Extension of terminal branches within the CNS, for example, transpires along a complex track around each hemisegment of the ventral nerve cord (Englund *et al*., 1999). Initially, it grows along the intersegmental nerve towards the nerve cord (see **Chapters 1.10** and **2.3**). At the CNS entry point, the terminal cell switches substrate to follow the segmental nerve to the ventral midline. During subsequent branch navigation into the nerve cord, the single ganglionic branch terminal cell turns at least five times along its journey to the target in order to penetrate this tissue.

The mechanisms underlying the local control of organotypic growth pattern in the vascular system of mouse skin appear to be analogous. Like the cells of the ganglionic branches, endothelial cells follow axons and glia, and these contacts determine both arterial differentiation and branching pattern (Mukouyama *et al*., 2002).

2.7.4. Embryonic Tracheal Development: Molecular Mechanisms

Each tracheal branch within a metamere (**Figure 1b**) has fixed cell numbers (**Figure 1c**) and characteristic tubular architectures (**Figure 2**), and grows on stereotyped tracks. Not surprisingly, the cells of the developing trachea display a prominent molecular diversity. This became first evident from the analysis of expression patterns of more than 100 tracheal enhancer trap markers (Samakovlis *et al*., 1996a). Apart from the general tracheal marker genes expressed in all tracheal cells, the expression of a characteristic group of tracheal marker genes is associated with the formation of each tube type, I–IV (**Figure 2**), and likely represents genetically distinct designs for tube construction. In addition, a number of markers display a regional or branch-specific expression within each metamere, or temporally regulated expression patterns during tracheal development that may relate to pathfinding, maturation, or tube size control of the individual branches (examples are shown in **Figure 5**). The molecular analysis of genes involved in tracheal development has revealed important roles for attractant and repellent signals, differentiation factors, and determinants for tube formation and dimensions, in tracheal development. These will be discussed below, and a table summarizing the genes involved in each process is presented within the relevant section.

2.7.4.1. Tracheal Cell Fate Specification

Tracheal development starts with the specification of the tracheal precursors in the ectoderm (**Table 1**). This relies on the combined action of two transcription factors, Trachealess (Trh), a basic helix–loop–helix (bHLH)-PAS domain protein, and Ventral veinless (Vvl, also termed Drifter), a POU-domain containing DNA binding protein (de Celis *et al*., 1995; Boube *et al*., 2000).

Trachealess expression identifies the clusters of epidermal tracheal precursor cells at stage 10 and, in *trh* mutants, the tracheal precursors fail to undergo the cytoskeletal rearrangements necessary for their invagination, and lack expression of many downstream genes necessary for branching (*btl, sms, rho, tdf,* and *peb*) (Isaac and Andrew, 1996; Wilk *et al*., 1996; Boube *et al*., 2000) (**Tables 3 and 8**). The PAS domain of Trh binds to the dARNT/HIFβ (*Drosophila* aryl hydrocarbon receptor nuclear translocator/hypoxia induced factor β) homolog Tango (Tgo), a ubiquitous protein with a more prominent tracheal expression (Ohshiro and Saigo, 1997; Sonnenfeld *et al*., 1997; Zelzer *et al*., 1997). The tracheal phenotypes of *tgo* zygotic mutants are weak, presumably due to the abundant maternal contribution of this gene product. These phenotypes become exaggerated in *trh* heterozygous embryos and, together with protein and DNA binding studies, indicate that Trh acts as a heterodimer with Tgo and is required for several steps during tracheal development.

Ectopic expression of *trh* is not sufficient to induce tracheal cell identity and placode formation throughout the ectoderm. This activity also requires the spatially restricted cofactor Vvl (Anderson *et al*., 1995; de Celis *et al*., 1995). In *vvl* mutants, tracheal cells invaginate only partially and fail to initiate migration and branching. Vvl is also required for the activation of an overlapping set of genes that are

activated by Trh (including *btl, sms, rho*, and *tkv*) (Anderson *et al*., 1996; Llimargas and Casanova, 1997) (**Tables 2 and 3**). The combined action of Vvl and Trh/Tgo is sufficient to induce ectopic activation of some (e.g., *btl*) but not all tracheal downstream genes in the epidermis. These results support a model where tracheal cell fates are induced by the cooperation of several factors rather than by the activation of a single tracheal master gene (Boube *et al*., 2000).

The expression domains of *trh* and *vvl* in the embryonic trunk appear to be controlled by the patterning genes that specify embryonic segmentation. The JAK/STAT (Janus kinase/signal transducer and activator of transcription) pathway is required for activation of *trh* expression. Decapentaplegic (Dpp; transforming growth factor (TGF)-β homolog) controls the *trh* expression boundaries along the dorsal–ventral axis, and Wingless (Wg; Wnt) is required for its correct expression along the anterior–posterior axis (de Celis *et al*., 1995; Wilk *et al*., 1996; Brown *et al*., 2001). The restriction of tracheal placodes to the central segments of the embryo, (T2–A8) depends on Spalt major (Salm), a negative regulator of tracheal cell differentiation. Salm is expressed in the anterior and posterior regions of the embryo, where it represses *trh*, *vvl*, and several other tracheal genes (Kuhnlein and Schuh, 1996; Boube *et al*., 2000). In *salm* mutants, an additional placode is acquired, which forms and invaginates anteriorly to the first tracheal pit.

An additional protein that affects *trh* expression is the zinc finger transcription factor Jing (Sedaghat *et al*., 2002). Jing expression in the trachea begins at the placode stage and persists throughout tracheogenesis and in *jing* mutants, fewer epidermal cells express *trh* and some of the tracheal precursors undergo apoptosis.

In summary, tracheal cell identity is determined by the cooperative action of at least two factors, Trh and Vvl. Their expression coordinates are set by embryonic patterning genes and maintained in the trachea through positive autoregulation. Trh and Vvl then activate genes necessary for placode invagination (like *rho*) and branching (like *btl*) (**Table 3**).

Already at stage 10, while the tracheal placode cells are specified, each tracheal placode is subdivided into dorsal and ventral subdomains. This regionalization is brought about by the selective expression of *salm* in the dorsal half of the placode (Franch-Marro and Casanova, 2002). Salm is necessary to repress the expression of genes like *unplugged* (*unpg*) (**Table 6**), which are normally only expressed in the ventral part of the trachea, namely the lateral trunk and ganglionic branches. In *salm* mutants, the dorsal trunk and dorsal branches develop like a mirror image of the lateral trunk and ganglionic branches. This is the second phase of Salm requirement in tracheal development, independent of its function in restricting Trh and Vvl expression in the placodes of the embryonic trunk. The regional requirement of Salm indicates that the tracheal placode is subdivided into domains with different cell fates prior to the activation of cell signaling pathways that allocate cells to different primary branches and direct their migration (see Sections 2.7.4.2 and 2.7.4.3.1).

2.7.4.2. Allocation of Cells to Different Primary Branches

Cell migration, tube formation, and elongation are the central cellular processes giving rise to the six primary tracheal branches, yet different primary branches present distinct tubular designs (type I in the dorsal trunk and transverse connective versus type II in the DB and the GB) (**Table 2**). Moreover, each of the branches attains a characteristic length and diameter and is composed by a fixed number of cells (Samakovlis *et al*., 1996a) (**Figure 1b**). The morphological diversity between the branches within a metamere is accompanied by regional and branch-specific gene expression patterns in each metamere.

The regional compartmentalization of cells in each tracheal pit requires the localized expression of Dpp (Vincent *et al*., 1997), Rhomboid (Rho; an intramembrane protease that generates active epidermal growth factor, EGF) (Wappner *et al*., 1997), Wingless (Wg) (Chihara and Hayashi, 2000; Llimargas, 2000), and Hedgehog (Hh) (Glazer and Shilo, 2001). Dpp is expressed in ectodermal stripes dorsal and ventral to the tracheal placode, setting up regional identities in the dorsal and ventral parts of the placode, that will give rise to DB, LTa, and LTp/GB (**Figure 6a**). Rho and Wg establish a central domain that gives rise to DT and VB (**Figure 6a**), whereas Hh, deriving from the cells just anterior to the placode, induces gene expression changes along the anterior–posterior axis.

The activation of these signaling pathways promotes a regional differentiation of the tracheal cells that is manifested by branch-specific expression of transcription factors. Decapentaplegic signaling is required in the DB, LTa and LTp/GB, and induces the expression of the transcription factors Knirps (Kni) and Knirps related (Knrl) in the responding tracheal cells (Chen *et al*., 1998) (**Figure 6a**). Selective inactivation of the Dpp signaling pathway does not impair oriented migration of the tracheal cells, but prevents the formation of type II tubes of the

Table 1 Genes required for tracheal cell fate specification[a]

Gene	CG number	Product	Expression	Phenotype	Function	References
decapentaplegic (dpp)	CG9885	TGF-β family member	In ectodermal stripes dorsal and ventral to the tracheal placode	Expansion of *dpp* expression domain recruits extra cells to the placode	Embryonic patterning gene, controls *trh* expression and positioning of placode along the DV axis; Dpp binds and activates its receptors Punt and Thickveins	Wilk *et al.* (1996)
domeless (dome) = master of marelle (mom)	CG14226	Transmembrane interleukin receptor homolog	Maternal, zygotic expression in tracheal pits	No tracheae in zygotic null mutants without maternal contribution	Receptor of the JAK–STAT signaling pathway required to initiate *trh* expression	Chen *et al.* (2002)
Epidermal growth factor receptor (Egfr) = DER = flb	CG10079	EGF receptor tyrosine kinase	Ubiquitously expressed	Impaired tracheal cell invagination	Receptor for activated Spitz (see *rho*)	Wappner *et al.* (1997), Llimargas and Casanova (1999)
hedgehog (hh)	CG4637	Patched ligand with a sonic hedgehog domain	Segment polarity expression	Reduced number of cells express *trh*, some cells fail to invaginate	Segment polarity gene; tracheal placode cell fate specification and invagination	Glazer and Shilo (2001)
jing	CG9403	Zinc finger transcription factor	Tracheal placode	Reduced number of placode cells, some undergo apoptosis: no VB, disrupted TC and DT	Assigns appropriate number of cells to the placodes	Sedaghat *et al.* (2002)
protein kinase B = Akt	CG4006	Protein kinase	Broad	Reduced *trh* expression and thus *btl* transcription	Activates and induces nuclear translocation of Trh by phosphorylation	Jin *et al.* (2001)
rhomboid (rho)	CG1004	Protease, 7 transmembrane domains	Tracheal placode	Impaired tracheal cell invagination	Cleaves and activates the EGF-like protein Spitz; required for complete invagination of tracheal placode	Llimargas and Casanova (1999)
spalt major (salm)	CG6464	Zinc finger transcription factor	Tracheal placode	Extratracheal placodes develop in terminal segments; DB and DT adopt ventral branch fates	Represses tracheal placode formation in terminal segments (by repressing *trh*, *vvl*, and other genes); specifies dorsal and ventral domains of the placode	Kuhnlein and Schuh (1996), Franch-Marro and Casanova (2002)

spitz (spi)	CG10334	EGF receptor ligand, TGF-α-like precursor	Ubiquitously expressed	DT and VB are missing or incomplete	Ligand for EGF receptor; cleaved and activated by Rho (see *rho*)	Wappner *et al.* (1997)
stat92E = *marelle (mrl)*	CG4257	Transcription factor with a SH2-domain	Maternal contribution	No tracheae in zygotic null mutants without maternal contribution	Acts downstream of Domeless in the JAK–STAT signaling pathway; required to initiate *trh* expression	Brown *et al.* (2001), Chen *et al.* (2002)
tango (tgo) = *dARNT* = *HIF*β	CG11987	bHLH-PAS domain heterodimerizes with Trh	Broadly embryonic expression	Variable tracheal defects	Specifies tracheal precursor cells in the ectoderm together with Trh; regulates expression of *rho*, *btl*, *sms*, *tdf*, and *peb*	Ohshiro and Saigo (1997), Sonnenfeld *et al.* (1997), Zelzer *et al.* (1997)
trachealess (trh)	CG6883	bHLH-PAS domain heterodimerizes with Tango	In all tracheal cells from stage 10 until end of embryogenesis	No tracheae; placodes fail to invaginate	Specifies tracheal precursor cells in the ectoderm together with Vvl; regulates expression of *rho*, *btl*, *sms*, *tdf*, and *peb*	Isaac and Andrew (1996), Wilk *et al.* (1996), Boube *et al.* (2000)
ventral veinless (vvl)/drifter	CG10037	POU domain transcription factor	Tracheal placode	Abnormal invagination; no primary budding	Specification of tracheal cell fate, together with Trh/Tgo; regulates expression of *rho*, *btl*, *stumps*, and *tkv*	Anderson *et al.* (1995, 1996), de Celis *et al.* (1995), Llimargas and Casanova (1997), Boube *et al.* (2000)
wingless (wg) = *wnt1*	CG4889	Wnt-1 family member	Segment polarity expression	Some tracheal cells fail to invaginate	Segment polarity gene, tracheal placode cell fate specification; sets dorsal and anterior–posterior limits on *trh* and *vvl* expression; required for invagination of some tracheal cells; ligand for Frizeled signaling pathway	Chihara and Hayashi (2000), Llimargas (2000)

[a]The expression pattern, phenotype, and function described for any gene in this table only refers to its role in tracheal cell fate specification, as does the chosen reference(s). The phenotype of genes with multiple functions during development may have been concluded from studies using hypomorphic or temperature sensitive alleles, expression of dominant negative alleles, or RNA interference (RNAi).

bHLH, basic helix–loop–helix; DB, dorsal branch; DT, dorsal trunk; DV, dorsoventral; EGF, epidermal growth factor; JAK–STAT, Janus kinase – signal transducer and activator of transcription; POU (see www.expasy.org/prositi); TC, transverse connective; TGF, transforming growth factor; VB, visceral branch.

Table 2 Genes involved in allocation of cells to different primary branches[a]

Gene	CG number	Product	Expression	Phenotype	Function	References
armadillo (arm)	CG11579	β-Catenin	Ubiquitously expressed	Arm(XM19): compromises *wg* signaling; gives a phenotype in DT (missing or reduced)	Downstream component of Wg signaling; required for branch specification	Chihara and Hayashi (2000), Llimargas (2000)
decapentaplegic (dpp)	CG9885	TGF-β family member	Expression in ectodermal stripes dorsal to, and two clusters ventral to the tracheal placode	Tracheal cells fail to migrate along the DV axis	Required for migration of tracheal branches in the DV axis (in DB, LTa, and LTp /GB), activates *kni* and *knrl* in these branches; Dpp binds and activates its receptors Pnt and Tkv	Vincent *et al.* (1997)
elbow B (elB)	CG4220	Zinc finger transcription factor	Pantracheal at stage 11, confined to DB and LT at stage 12	Delayed and abnormal migration of LT and DB cells	Necessary for correct LT and DB cell identity; suppresses VB and DT fate in these cells, probably heterodimerizes with Noc	Dorfman *et al.* (2002a)
Epidermal growth factor receptor (EGFR) = DER = flb	CG10079	EGF receptor tyrosine kinase	Ubiquitously expressed	DT and VB are missing or incomplete	Receptor for activated Spi (see *rho*)	Wappner *et al.* (1997), Llimargas and Casanova (1999)
hedgehog (hh)	CG4637	Patched ligand with a sonic hedgehog domain	Segmental stripes; punctuate pattern overlapping anterior pit cells	Impaired migration of all tracheal branches to different extent	Dorsal branch identity gene; Hh is required for expression of anterior tracheal markers	Glazer and Shilo (2001)
knirps (kni)	CG4717	Zinc finger transcription factor	Placode (stage 11), DB, LT, GB, and VB	DB fails to form, cells remain in DT	DB identity gene; represses *salm* expression	Chen *et al.* (1998)
knirps-related (knrl)	CG4761	Zinc finger transcription factor	Placode (stage 11), dorsalmost tracheal cells (future DB)	DB fails to form, cells remain in DT	DB identity gene; represses *salm* expression	Chen *et al.* (1998)
Mothers against dpp (Mad)	CG12399	Transcription factor		Similar phenotype as when blocking Dpp signaling pathway	Activated by Tkv and Put, induces expression of *kni* and *knrl*	Newfeld *et al.* (1997), Chen *et al.* (1998), Raftery and Sutherland (1999)
no ocelli (noc)	CG4491	Zinc finger transcription factor	Tracheal pits from stage 11; ubiquitous from stage 13	Delayed and abnormal migration of LT and DB cells	Necessary for correct LT and DB cell identity; suppresses VB and DT fate in these cells, probably heterodimerizes with Elb	Dorfman *et al.* (2002a)

punt (put)	CG7904	Type II TGF-β receptor family, serine-threonine kinase		(See *dpp*)	Dpp-receptor; activation of Put leads to phosphorylation of Mad, which induces expression of *kni* and *knrl* (see *dpp*)	Affolter *et al.* (1994b), Ruberte *et al.* (1995), Vincent *et al.* (1997)
rhomboid (rho)	CG1004	Protease, 7 transmembrane domains	Central domain of tracheal placode	Affects the direction of tracheal migration; DT and VB are not formed	Cleaves and activates the EGF-like protein Spi; assigns DT and VB cell fate (central domain of placodes); promotes *salm* expression	Wappner *et al.* (1997)
spalt major (salm)	CG6464	Zinc finger transcription factor	Future DT	No DT; DT cells migrate dorsally together with DB	Activated by Wg/Wnt and EGF signaling, repressed by Kni and Knrl; Salm is necessary for AP cell migration	Llimargas (2000), Kuhnlein and Schuh (1996), Boube *et al.* (2000)
spitz (spi)	CG10334	EGF receptor ligand, produced as inactive transmembrane precursor	Ubiquitously expressed	DT and VB are missing or incomplete	Cleaved and activated by Rho (see *rho*)	Wappner *et al.* (1997), Llimargas and Casanova (1999)
star (S)	CG4385	Type II single transmembrane domain protein	Ubiquitously expressed	DT and VB are missing or incomplete	Required for Spi activation, probably transports inactive Spi from endoplasmic reticulum to Rho-containing organelles	Wappner *et al.* (1997), Tsruya *et al.* (2002)
thickveins (tkv)	CG14026	Type I TGF-β receptor family, serine-threonine kinase		(See *dpp*)	Dpp-receptor; activation of Tkv leads to phosphorylation of Mad, which induces expression of *kni* and *knrl* (see *dpp*)	Affolter *et al.* (1994b), Ruberte *et al.* (1995), Vincent *et al.* (1997)
wingless (wg) = *wnt1*	CG4889	Wnt-1 family member	Two ectodermal patches dorsal/ lateral to the placode	DT is partially lost or fails to migrate	Wg is required for differentiation of DT (vs. VB) through activation of *spalt*; ligand for Frizeled signaling pathway	Chihara and Hayashi (2000), Llimargas (2000)
Wnt oncogene analog 2 (Wnt2)	CG1916	Wnt family member	Dorsal to the placode at stages 10 and 11	No defects in *wnt2* mutants, but *wg*:*wnt2* mutants display enhanced *wg* phenotype	Ligand for Frizeled signaling pathway	Llimargas and Lawrence (2001)

[a]The expression pattern, phenotype, and function described for any gene in this table only refers to its role in allocation of cells to different primary branches, as does the chosen reference(s). The phenotype of genes with multiple functions during development may have been concluded from studies using hypomorphic or temperature sensitive alleles, expression of dominant negative alleles, or RNA interference (RNAi).

AP, anteroposterior; DB, dorsal branch; DT, dorsal trunk; EGF, epidermal growth factor; GB, ganglionic branch; LT, lateral trunk; LTa, lateral trunk anterior; LTp, lateral trunk posterior; TGF, transforming growth factor; VB, visceral branch.

Table 3 Genes involved in primary branching[a]

Gene	CG number	Product	Expression	Phenotype	Function	References
anterior open (aop) = AOP/ Yan = yan	CG3166	ETS domain transcriptional repressor	Begins at stage 11; dynamic expression in subset of tracheal cells		Repressor of *btl* expression; Aop is inactivated in the presence of Bnl–Btl signaling in growing tracheal branches	Ohshiro *et al.* (2002)
armadillo (arm)	CG11579	β-Catenin	Ubiquitously expressed	Arm(XM19): compromises Wg signaling, GB misrouted	Downstream component of Wg signaling; required for GB guidance probably through the canonical Wg–Wnt signaling pathway	Llimargas (2000)
branchless (bnl)	CG4608	Homolog of mammalian FGF	Prior to and during primary branching in cell clusters surrounding each sac	No primary branching	Bnl is a chemoattractant, which activates Btl in tracheal cells, guiding their migration	Sutherland *et al.* (1996)
breathless (btl)	CG6714	Homolog of FGF receptor, a receptor tyrosine kinase	Activated in tracheal cells from stage 10	No primary branching	The only known receptor for Bnl; Bnl–Btl signal transduction activates the Ras/MAPK pathway; activated by Trh/Tango and Vvl	Glazer and Shilo (1991), Klambt *et al.* (1992), Reichman-Fried and Shilo (1995)
cdc42	CG12530	Ras GTPase superfamily		No branch extension	May act downstream of Bnl to promote cytoplasmic cell extensions during branch growth	Wolf *et al.* (2002)
corkscrew (csw)	CG3954	Nonreceptor protein tyrosine phosphatase		Severe interruption of primary branch outgrowth	Component of RTK signaling pathway	Perkins *et al.* (1996)
crumbs (crb)	CG6383	Transmembrane protein with EGF, RGD, and laminin A repeats	In trachea from early stage 12 onwards	Affects branch outgrowth and fusion	Required for epithelial polarity and integrity	Tepass *et al.* (1990)
decapentaplegic (dpp)	CG9885	TGF-β family member	Ectodermal patch dorsal to the tracheal pocket	DB cells fail to migrate dorsally	Not required for initial Bnl-induced migration, but to maintain DB extension; Dpp binds and activates its receptors Pnt and Tkv	Ribeiro *et al.* (2002)
Heparan sulfate 6-*O-sulfotransferase (dHS6st)*	CG17188	Enzyme catalyzing heparan sulfate proteoglycan biosynthesis	Selectively in tracheal cells from stages 10 to 12	No primary branching	Required for synthesis of HSPGs, which function as coreceptors mediating formation of active FGF/FGFR signaling complex	Kamimura *et al.* (2001)
l(1) tracheae lacking (l(1)tl)				No main trunks		Manning and Krasnow (1993)
leak (lea) = roundabout 2	CG5481	Slit receptor	All cells at stage 11, DT, DB, and VB at stage 13, DB1 and DB2 at stage 16	Late DB and GB migration disrupted	Mediates tracheal attractant function of Slit	Englund *et al.* (2002)

multiprotein bridging factor 1 (mbf1)	CG4143	Transcription cofactor with a HTH domain	Broad	Mutants become haploinsufficient for *tdf* (tracheal breaks)	Transcriptional coactivator for Tdf	Liu *et al.* (2003b)
protein kinase B = Akt	CG4006	Protein kinase	Broad		May induce cytoskeletal rearrangements; phosphorylates Trh	Jin *et al.* (2001)
Rac1	CG2248	Ras GTPase superfamily	Ubiquitous in all cells, associated with plasma membranes	Increased levels and more lateral distribution of cadherin/catenin complexes; broken DT, misguided DB, no terminal branches	Regulates the amount of E-cad deposited at apical junctions; Rac-activation may be part of Bnl-induced cell motility	Chihara *et al.* (2003)
Rac2	CG8556	Ras GTPase superfamily	(See Rac1)	(See Rac1)	(See Rac1)	Chihara *et al.* (2003)
raw	CG12437	No conserved domains	Broad in epithelial cells	Reduced primary branching	Required in tubular epithelia for cells to assume specialized shapes; possible role for Raw in organizing the actin cytoskeleton	Jack and Myette (1997), Blake *et al.* (1999)
RhoA	CG8416	Ras GTPase superfamily		Dominant negative RhoA; inhibits lumen formation	Necessary for lumen formation; regulation of the cytoskeleton during cell migration; may function upstream of Shot	Lee and Kolodziej (2002)
ribbon (rib)	CG7230	BTB transcription factor with a Pipsqueak DNA-binding domain	All tracheal cells	No primary branching	Required for primary branch lumen growth and cell body movement	Bradley and Andrew (2001), Shim *et al.* (2001)
rolled (rl) = MAPK	CG12559	MAP kinase, protein serine-threonine kinase	Activated MAPK is detected in leading cells of primary branches		Activated by Bnl–Btl signaling; is thought to mediate part of Bnl-induced branch migration	Gabay *et al.* (1997)
slit (sli)	CG8355	Extracellular matrix protein, Robo and Robo2 ligand	In the CNS midline and many other tissues surrounding growing branches	Late DB and GB migration is disrupted	Cell migration signal; activates Robo receptors expressed in tracheal cells to guide DB and GB branch migration	Englund *et al.* (2002)
stripe (sr)	CG7847	Zinc finger transcription factor	Dynamic expression in ectodermal cell clusters during primary branch growth	Delayed migration of DT, LTa, and GB cells	Acts nonautonomously to guide branch growth possibly by providing cues for branch migration	Dorfman *et al.* (2002b)
stumps (sms)/dof/ heartbroken (hbr)	CG18485	Novel intracellular protein, similar to PI3-kinase adaptor		No primary branching	Promotes FGF-directed cell migration; probably an adaptor between FGFR and downstream effectors	Michelson *et al.* (1998), Vincent *et al.* (1998), Imam *et al.* (1999), Dossenbach *et al.* (2001)

Continued

Table 3 Continued

Gene	*CG number*	*Product*	*Expression*	*Phenotype*	*Function*	*References*
sugarless (sgl)	CG10072	Enzyme catalyzing heparan sulfate proteoglycan biosynthesis		No primary branching	Required for synthesis of HSPGs, which function as coreceptors mediating formation of active FGF/FGFR signaling complex	Lin *et al.* (1999)
sulfateless (sfl)	CG8339	Enzyme catalyzing heparan sulfate proteoglycan biosynthesis		No primary branching	Required for synthesis of HSPGs, which function as coreceptors mediating formation of active FGF/FGFR signaling complex	Lin *et al.* (1999)
trachea broken (tbr)				Broken or missing parts of DT with compensatory branching around breaks		Manning and Krasnow (1993)
trachea defective (tdf) = *apontic (apt)*	CG5393	Transcription factor, a bZip protein with a Myb-type DNA binding domain	All tracheal cells from stage 10	Inhibits tracheal cell migration; lack of both maternal and zygotic contribution leads to lack of pit formation	Invagination and branch growth; expression is Trh dependent	Eulenberg and Schuh (1997)

[a]The expression pattern, phenotype and function described for any gene in this table only refers to its role in primary branching, as does the chosen reference(s). The phenotype of genes with multiple functions during development may have been concluded from studies using hypomorphic or temperature sensitive alleles, expression of dominant negative alleles or RNAi. CNS, central nervous system; DB, dorsal branch; DT, dorsal trunk; ETS, erythroblast transformation specific; FGF, fibroblast growth factor; FGFR, fibroblast growth factor receptor; GB, ganglionic branch; GTPase, guanosine triphosphatase; HSPGs, heparan sulfate proteoglycans; LTa, lateral trunk anterior; MAP, mitogen activated protein; VB, visceral branch; BTB, HTH, Myb, RGD (see www.expasy.org/prositi).

DBs (Ribeiro *et al.*, 2002). Activation of EGF by Rho expression in a central subset of tracheal cells is required, first, for tracheal cell invagination (Llimargas and Casanova, 1999), and then for proper development of the DT and VB. The distinction of DT and VB cells is provided by Wg signaling, which induces DT cell fates. Both Wg and EGF receptor (EGFR) signaling appear to promote

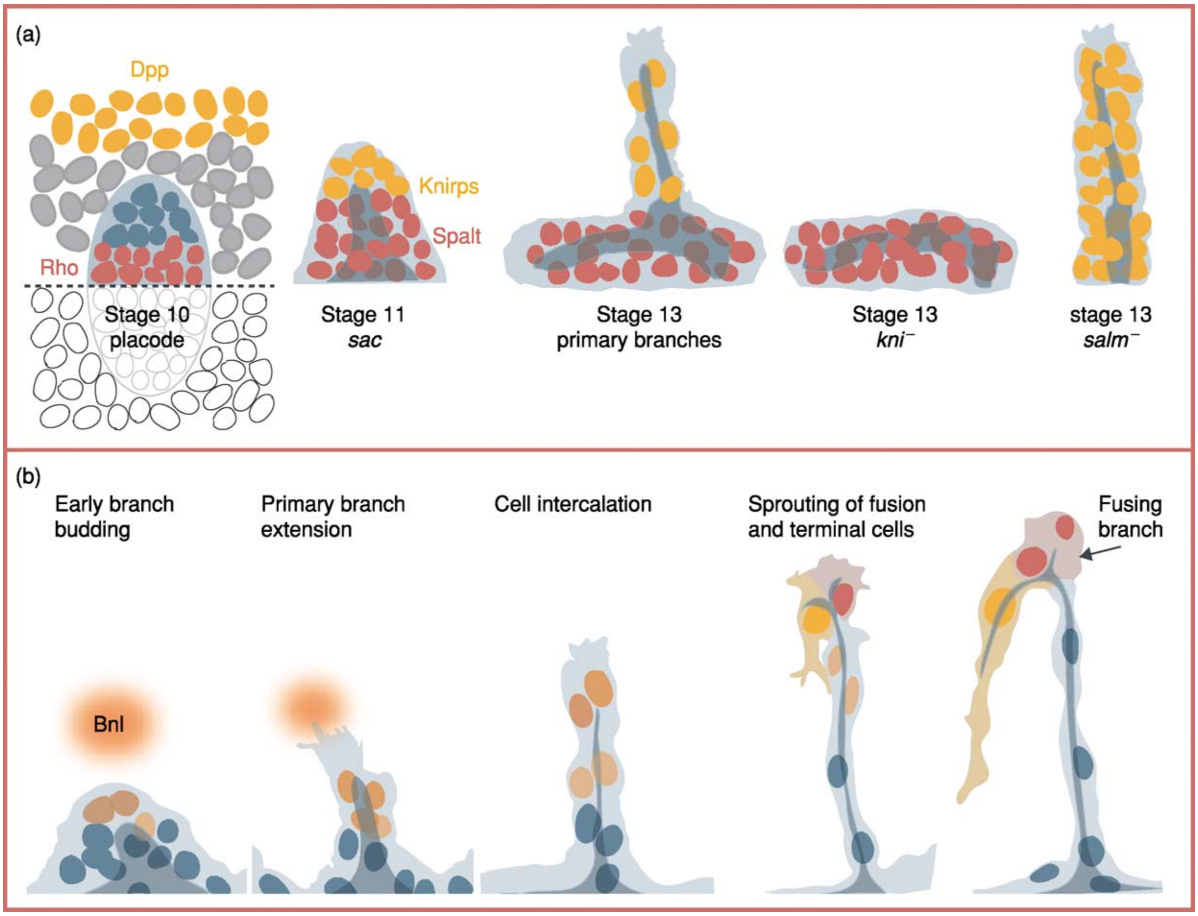

Figure 6 Specification and cellular dynamics of the developing dorsal branch. (a) Model of dorsal branch specification by Spalt, Decapentaplegic (Dpp), and Rhomboid (Rho, a protease that generates active epidermal growth factor (EGF)). Early expression of Spalt subdivides the placode (oval in stage 10) into a dorsal (upper) and a ventral (lower; not colored in this figure) domain. At stage 10, Dpp (yellow) is expressed in the dorsal ectoderm (gray nuclei depict other ectodermal cells). Dpp signals to the dorsal part of the placode, the presumptive DB, DTa, and DTp, to induce expression of the transcription factors Knirps (Kni) and Knirps related (Knrl) in the responding tracheal cells (yellow in stages 11 and 13). In turn, Kni and Knrl repress *salm* (red nuclei) in their domain of expression. Activation of *EGF* by *Rho* expression (red) in a central domain of tracheal placode cells at stage 10 is first required for tracheal cell invagination, and then for proper development of the DT and the VB and activation of *salm* expression. The differentiation between DT and VB cells is mediated by Wg signaling (not shown), which induces DT cell fates. In the absence of Kni and Knrl (stage 13: kni$^-$), the DB does not form and the cells integrate into the DT. In *spalt* mutants (stage 13: salm$^-$), the DT does not form and the cells integrate into DB. (b) Cell dynamics of DB development. The DB arises from cellular rearrangements that generate a dorsal bud within each epithelial sack. First panel: cells at the tip of the bud (brown) respond to Branchless (Bnl; orange), and this leads to subsequent branch extension. Six cells in each hemisegment are destined to follow Bnl-induced migration in the dorsal orientation. Second panel: broad cytoplasmic protrusions emanate from the leading cells towards the Bnl chemoattractant, followed by cellular movements and lumen growth, generating a type I tube. Third panel: the tip cells express the pantip marker Pnt (brown nuclei) in response to the Bnl signal. Dorsal branch elongation proceeds, as the four proximal cells in the branch change their positions from facing each other around the lumen to lying in a row. Fourth panel: the two tip cells differentiate into one terminal cell (yellow) and one fusion cell (red). Intercalation of the four proximal cells to produce a type II tube is completed, and the two tip cells begin to form unicellular branches by extending broad cellular processes and moving their cell bodies away from the primary branch. The dorsal branch lumen bifurcates to provide the initial lumen bud within each of the two tip cells. Towards the end of embryogenesis, the fusion cell has formed a hollow tube and contacted its partner in the contralateral metamere to connect the two at the dorsal midline by a type III tube (two red nuclei). The terminal cell has formed a long subcellular tube extension (type IV tube) and continues to grow towards its target. Fifth panel: the final stalk of the dorsal branch consists of only three cells, because the most proximal cell retracts back into the dorsal trunk.

activation of the transcription factor Salm, and Salm is repressed by Kni and Knrl (Chen *et al.*, 1998) (**Figure 6a**). Additional transcription factors like Unplugged (Unpg), Elbow (Elb), and No ocelli (Noc) are also required for the outgrowth of a subset of branches, but their connection to the emerging scheme is unclear (Chiang *et al.*, 1995; Dorfman *et al.*, 2002a).

The role of the regional placode specification in primary branch migration is beginning to be revealed. Inhibition of Dpp signaling in tracheal cells does not affect Bnl-induced outgrowth and filopodial activities in the tip cells of the DB (see Section 2.7.4.3.1). Instead, the cells fail to migrate the full distance and eventually retract back into the dorsal trunk (Ribeiro *et al.*, 2002). Furthermore, the spatial expression of Kni, Knrl, and Salm is required for branch-specific expression of PS1 integrin in VB cells, which is necessary for correct migration of these cells along the midgut (Boube *et al.*, 2001). The regional differentiation may, therefore, aid oriented branch growth towards the localized sources of Bnl, by preparing the cells for migration along distinct substrates. It may also determine the characteristic dimensions and structure of each tube.

2.7.4.3. Branch Formation and Guidance

Following the establishment of regional and branch-specific identities within the tracheal placode, the tracheal cells begin an extraordinary morphogenetic process to form the elaborate tracheal network. These tubulogenic events involve oriented cell migration, and a hierarchic genetic program that determines cell fate choices induced by signals from the extra tracheal environment.

2.7.4.3.1. Primary branches: the formation and growth of multicellular tubes What determines where new branches form and their direction of growth? For the budding and oriented outgrowth of primary branches, these answers lie in a signal transduction pathway initiated by Branchless (Bnl), a homolog of the secreted fibroblast growth factor (FGF) family (**Table 3**). At stage 10, just before primary branching commences, all tracheal cells in each metamere begin to express the tyrosine kinase receptor Breathless (Btl), a homolog of mammalian FGF receptors (Glazer and Shilo, 1991; Klambt *et al.*, 1992). Bnl, the Btl ligand, is expressed in cell clusters surrounding each individual tracheal metamere (Sutherland *et al.*, 1996). Every cluster of Bnl-expressing cells will activate Btl in the nearby tracheal cells, which respond by oriented cell migration towards the signaling source, and the formation of a primary branch (**Figure 6b**). Hence, a typical metamere receives Bnl from six surrounding cell clusters at stages 11–12. The expression of *bnl* is dynamically regulated and turned off when the respective primary branch reaches the cluster (**Figure 6b**). For some branches, the Bnl source reappears at a new location further along the migratory track, promoting further extension of the branch.

Embryos mutant for *bnl* or *btl* do not form primary branches, and their embryonic trachea consists of 20 unconnected elongated sacks of tracheal cells. Localized ectopic expression of Bnl in epidermal cells can redirect primary branch growth towards its new site of expression in the epidermal clusters (Sutherland *et al.*, 1996). Thus, Bnl is a chemoattractant that promotes and guides primary branch growth; its temporal and spatial expression establishes the pattern of primary branching.

What determines the expression pattern of Bnl? It is likely that the *bnl* promoter contains complex control elements that allow independent transcription in cell clusters positioned at several distinct anterior–posterior and dorsal–ventral coordinates within each segment. The dorsal patch of *bnl* expression, for example, is absent in mutants for *dpp*, demonstrating an independent control of *bnl* expression in this cluster (Vincent *et al.*, 1997).

Breathless expression is also regulated in primary branches. After its onset in all tracheal cells at stage 10, its expression declines in DT and TC during stage 12 and, at late stage 13, it is restricted almost completely to growing branches such as the DB, VB, LTa, and LTp (Ohshiro *et al.*, 2002). It appears that Btl expression during stages 12 and 13 is regulated by a positive feedback loop: Bnl–Btl signaling activates Rolled (Rl), mitogen activated protein kinase (MAPK) (see below), which in turn destabilizes Anterior-open (Aop), a repressor of Btl expression, and thus activates Btl expression. In this way a continuous supply of Btl receptor to membranes of the extending tracheal cells is ensured.

Additional molecules that act in the Bnl–Btl signal transduction pathway, either upstream or downstream of *btl* activation, have been identified. The intracellular protein Downstream-of-FGF receptor (FGFR) (Dof; also known as Stumps and Heartbroken) is specifically required for FGF signal transduction in *Drosophila*, and *dof* mutants show a tracheal phenotype similar to that of *btl* and *bnl* (Michelson *et al.*, 1998; Vincent *et al.*, 1998; Imam *et al.*, 1999; Dossenbach *et al.*, 2001). The *dof* gene encodes a novel protein that is expressed in the developing trachea and is enriched at the plasma membrane. As it contains potential docking sites for several intracellular signaling proteins, Dof may function as an adapter that couples FGFR signaling to

downstream effectors in cell migration. Mutations in either of the two genes *sugarless* (*sgl*) and *sulfateless* (*sfl*), which encode enzymes that synthesize heparan sulfate proteoglycans (HSPGs), also block activation of primary branch outgrowth (Lin *et al.*, 1999). The HSPGs function as coreceptors mediating formation of active FGF–FGFR signaling complexes (Pellegrini, 2001) and, in *sgl* and *sfl* mutants, MAPK activation in the trachea is blocked, but can be re-established by overexpression of the Bnl ligand.

A third gene involved in HSPG biosynthesis is *heparan sulfate* 6-O-*sulfotransferase* (*dHS6ST*). The dHS6ST protein belongs to a class of enzymes that locally modify HSPGs, and is selectively expressed in tracheal cells from stage 10 to 12 (Kamimura *et al.*, 2001). Inhibition of dHS6ST activity by RNA interference (RNAi) disrupts primary branch outgrowth and blocks MAPK activation, suggesting that a particular HSPG structure is required for Bnl signaling.

The molecular mechanisms downstream of Btl activation and their direct link to primary branch growth (**Figure 6b**) are poorly understood, but the first clues are now emerging. The initial extension of broad cellular protrusions, containing filamentous actin, requires active Bnl–FGF signaling (Ribeiro *et al.*, 2002). As active MAPK is present in the leading cells of primary branches (Gabay *et al.*, 1997), but reduced or absent in mutants for *bnl*, *btl*, and *dof*, part of the Bnl-induced branch migrations is most likely conveyed through activation of MAPK (Vincent *et al.*, 1998) (**Table 4**). In support of this, ectopic tracheal expression of activated forms of Ras and Raf partially rescues the primary branch growth defects in *btl* mutants. Furthermore, mutants for *corkscrew* (*csw*), which encodes a nonreceptor protein tyrosine phosphatase that can activate Ras, show severe defects in primary branch outgrowth (Reichman-Fried *et al.*, 1994; Perkins *et al.*, 1996).

The initial dynamic filopodial extensions towards the Bnl source also appear to involve the Rho family guanosine triphosphatases (RhoA, Cdc42, Rac1, and Rac2), which are instrumental in the regulation of the cytoskeleton during cell migration. Overexpression of constitutively active Cdc42 in the trachea induces filopodial extensions, whereas expression of a dominant negative form of Cdc42 impedes branch extension (Wolf *et al.*, 2002). Further cell movement and growth of apical cell surface during primary branching seem to require transcriptional regulation. The putative transcription factor, Ribbon (Rib), is expressed in all tracheal cells (Bradley and Andrew, 2001; Shim *et al.*, 2001) and, in *rib* mutants, filopodia extend toward the Bnl source, but cell body movement and lumen growth are aborted. The *rib* gene may be directly activated by the Bnl–Btl signal transduction pathway (perhaps via MAPK), and Rib may translate the Bnl signal into cell movement and apical membrane growth. Alternatively, it may act in parallel to the Bnl–FGF-induced branch growth, to accommodate these aspects of branch extension once the cells have received the Bnl signal.

Another putative transcription factor, Trachea defective (Tdf), is also required for primary branch outgrowth. The Tdf protein is expressed in the developing trachea, from the placode stage, in a *trh*-dependent manner and, in zygotic *tdf* mutants, primary branching is impeded, but the formation of tracheal placodes, invagination of tracheal cells, and generation of tracheal sacs occur normally (Eulenberg and Schuh, 1997). Removal of maternal Tdf, however, prevents the invagination of the tracheal precursors from the epidermis, indicating that Tdf is required for tracheal cell rearrangements underlying both invagination and branch growth.

Primary branches grow toward, along, and across different cell types to reach their targets. Is the chemoattractant activity of Bnl sufficient to specify the migratory paths taken by different branches and the extent of branch elongation? Primary branch elongation may in part be influenced by the nature of Bnl expression, since localized Bnl sources cease to reappear at new locations further along the migratory track during primary branch growth (Sutherland *et al.*, 1996).

Accumulating evidence from the analysis of mutants affecting the outgrowth of primary branches also indicates that the branches require branch-specific migratory cues in addition to the localized sources of Bnl. Such a guiding function maybe provided by the dynamic expression of Slit (Sli), a phylogenetically conserved cell migration signal, in many of the tissues surrounding the developing trachea. Mutations in *slit* and one of its three fly receptors, *roundabout 2* (*robo2*), hamper the outgrowth of the dorsal, ganglionic, and visceral primary branches (Englund *et al.*, 2002). Ectopic Slit is sufficient to redirect and attract new primary branches towards its ectopic site of expression, and this phenotype is dependent on the expression of the right combination of Robo and Robo2 receptors in the receiving tracheal branches. However, the long-range attractant function of Slit is not sufficient to induce primary branching in the absence of functional Bnl signaling, suggesting a sequential requirement in the activation of different signaling pathways during the migration of primary branches.

Another prerequisite for primary branch migration is cell adhesion to appropriate migration

Table 4 Genes required for secondary branching[a]

Gene	*CG number*	*Product*	*Expression*	*Phenotype*	*Function*	*References*
anterior open (aop) = AOP/ Yan = yan	CG3166	ETS domain transcriptional repressor	Stage 11 on, dynamic expression in subset of tracheal cells		Repressor of late *btl* expression; Aop is inactivated in the presence of Bnl–Btl signaling in growing tracheal branches	Ohshiro *et al.* (2002)
branchless (bnl)	CG4608	Homolog of mammalian FGF	Ceases as primary branches reach the *bnl* source	No induction of secondary branch genes	Controls secondary branch cell specification by inducing expression of secondary branch gene expression; induces expression of *sty*	Sutherland *et al.* (1996)
breathless (btl)	CG6714	Homolog of FGF receptor, a receptor tyrosine kinase	Upregulated in tip cells by positive feedback loop	No induction of secondary branch genes	Bnl receptor (see *bnl*)	Reichman-Fried and Shilo (1995), Lee *et al.* (1996)
pointed (pnt)	CG17077	ETS domain transcription factor	First in primary branch tip cells, becomes restricted to secondary branch cells, then to terminal cells	No secondary branching	Secondary branch gene, induced by Bnl; maintains *btl* expression, induces expression of *sty* and *bs*, inhibits *esg* expression	Samakovlis *et al.* (1996a), Hacohen *et al.* (1998), Ohshiro *et al.* (2002)
rolled (rl) = MAPK	CG12559	MAP kinase, protein serine-threonine kinase	Activated MAP kinase is detected in tip cells (primary branch)		Activated by Bnl–Btl signaling; destabilizes Aop and activates Pnt, thus upregulating *btl* expression	Gabay *et al.* (1997)
sprouty (sty)	CG1921	Novel protein with cystein-rich motif; localizes to cell membrane	Secondary branch cells	Extra terminal branches due to overactivation of the Bnl signaling pathway in stalk cells	Intracellular inhibitor of Ras/MAP kinase pathway, and acts as branching inhibitor in the trachea; reported to act cell nonautonomously; induced by the Bnl pathway	Hacohen *et al.* (1998)

[a]The expression pattern, phenotype and function described for any gene in this table only refers to its role in secondary branching, as does the chosen reference(s). The phenotype of genes with multiple functions during development may have been concluded from studies using hypomorphic or temperature sensitive alleles, expression of dominant negative alleles or RNAi. ETS, erythroblast transformation specific; FGF, fibroblast growth factor; MAP, mitogen activated protein.

substrates, which is necessary for dorsal trunk formation. Despite the fact that the extension of DTa and DTp is relatively short and straight (towards a localized source of Bnl between the two buds), their correct migration and subsequent branch fusion require a single cell of mesodermal origin, the bridge cell, which is located at the position where the two branches meet (Wolf and Schuh, 2000). Bridge cells are distinguished by their selective expression of the transcription factor Hunchback (Hb), and, in *hb* mutants, bridge cells undergo apoptosis resulting in DT fusion defects (**Table 5**). As ectopic expression of *hb* in additional cells, close to the bridge cells, interferes with DT formation, Hb appears to be required not only for bridge cell viability, but also for its function in providing an adhesion-dependent guiding post for branch migration. Thus, despite the key role of the Bnl chemoattractant in primary branching, there is a requirement for additional signals that regulate the cellular dynamics of the tracheal epithelium and its interactions with surrounding tissues.

2.7.4.3.2. Sprouting of unicellular branches Within the interim of stage 14, 23 of the 80 cells in the typical tracheal metamere form unicellular sprouts that emanate from the primary branches (**Table 4**). The cells that will form these secondary branch sprouts are molecularly recognized at stage 13 due to their selective expression of pantip marker genes (Samakovlis *et al*., 1996a) (see also **Figure 5**). Pantip gene expression is induced by the same Bnl signal that patterns the primary branches (**Figure 6b**). Most pantip genes are activated already during stage 12 in the tip cells of primary branch buds. These are the cells closest to the Bnl signaling source and, during stage 13, pantip gene expression becomes defined to the exact number of cells that will produce the unicellular secondary sprouts. Several pantip genes are not induced in *bnl* and *btl* mutants, and ubiquitous ectopic Bnl expression activates the expression of secondary and terminal branch genes throughout the tracheal system, causing a hypersprouting phenotype (Lee *et al*., 1996; Sutherland *et al*., 1996). Thus, the potential to activate pantip genes and form unicellular sprouts appears to be a common feature of all tracheal cells, but is selected and restricted by the localized *bnl* expression within each hemisegment.

How is the expression of secondary branch genes restricted to a precise number of cells at stage 13? As Bnl signaling promotes degradation of Aop, which in turn represses *btl* expression (Ohshiro *et al*., 2002), this positive feedback loop restricts the number of cells that perceive and can respond to the Bnl signal during stages 12 and 13. The Bnl signaling also activates expression of genes that limit secondary branching. Sprouty (Spry), an evolutionary conserved protein with a novel cysteine-rich motif, is induced by Bnl and antagonizes Btl and other receptor tyrosine kinase (RTK) signaling pathways (Hacohen *et al*., 1998; Casci *et al*., 1999; Kramer *et al*., 1999; Reich *et al*., 1999). Tracheal *spry* expression is detected in primary branches, as they begin to bud, and is subsequently maintained at high levels in the tip of branches, i.e., in the cells that form secondary branches. In the trachea, Spry acts on cell nonautonomously to stop neighboring cells from expressing secondary branch genes and, in *spry* mutants, more cells form secondary sprouts due to ectopic activation of the Bnl signaling pathway in them. The Spry protein localizes to the cell membrane and appears to interact with canonical members of the RTK pathway upstream of MAPK. However, the mechanism of its cell nonautonomous action in the trachea remains unclear.

One well-studied secondary branch target of the Bnl/Btl signaling pathway is the gene encoding the erythroblast transformation specific (ETS) family transcription factor Pointed (Pnt). In *pnt* mutants, the framework of primary branches develops normally, but no secondary sprouts form. The Pnt protein plays an essential role in the selection and identity of cells that will undergo sprouting: it is required to maintain the expression of Btl in primary branch tip cells (Ohshiro *et al*., 2002), and also induces the expression of *spry* (Hacohen *et al*., 1998). In addition, it promotes the next stage of branching by activating transcription of (*DSRF Drosophila serum response factor* homolog) (**Table 6**) and repressing the expression of the fusion branch gene *escargot* (*esg*) (Samakovlis *et al*., 1996a) (**Table 5**) (see Sections 2.7.4.3.3 and 2.7.4.3.4). As no secondary branches are observed in *pnt* mutants, it is possible that Pnt also regulates cellular components required for the controlled cell shape changes that occur during secondary sprouting.

The selected secondary branch cells are further differentiated into fusion cells or terminal cells by intricate cellular cross talk, involving the reiterated use of Bnl, Dpp, Wg, and the activation of Notch (N) signaling (Ikeya and Hayashi, 1999; Llimargas, 1999, 2000; Steneberg *et al*., 1999; Chihara and Hayashi, 2000) (**Table 5**). Localized expression of *bnl* and *wg* in nearby tissues activates expression of the fusion gene *esg* in individual cells at the ends of primary branches, as well as the expression of *Delta* (*Dl*) (**Table 5**). In the dorsal branch, Dpp signaling is also involved in the activation of *esg*. Delta activates *Notch* in the neighboring cells,

Table 5 Genes required for branch fusion[a]

Gene	CG number	Product	Expression	Phenotype	Function	References
armadillo (arm)	CG11579	β-Catenin	Ubiquitously expressed	No branch fusions	Downstream component of Wg signaling; required for branch fusion and *esg* expression, probably through Wg–Wnt signaling pathway	Llimargas (2000), Chihara and Hayashi (2000)
branchless (bnl)	CG4608	Homolog of mammalian FGF	Ceases as primary branches reach the *bnl* source	No induction of secondary branch genes	Promotes fusion gene expression	Ikeya and Hayashi (1999)
decapentaplegic (dpp)	CG9885	TGF-β family member	In cell cluster dorsal to DB	No DB fusion	Promotes fusion gene expression in DB	Steneberg *et al.* (1999)
Delta (Dl)	CG3619	Transmembrane protein with EGF repeats and cell adhesion function	Fusion cells	Various fusion defects	Fusion gene; activates Notch in neighboring cells, thereby preventing these from becoming fusion cells	Ikeya and Hayashi (1999), Llimargas (1999), Steneberg *et al.* (1999)
dysfusion (dys)	CG12561	HLH-PAS transcription factor	Fusion cells	Impaired fusion of DB, LT, and GB	Heterodimerizes with Tgo; required for fusion of DB, LT, and GB; activated by Esg.	Jiang and Crews (2003)
escargot (esg)	CG3758	Zinc finger transcription factor	All fusion cells	DB and LT fusion events are disrupted	Induces expression of later fusion genes such as *shg*, *mbo*, *hdc*, and *dys* in DB, LTa, and LTp; represses the expression of the terminal branch gene *bs*	Samakovlis *et al.* (1996b), Tanaka-Matakatsu *et al.* (1996)
fear-of-intimacy (foi)	CG6817	Transmembrane protein, zinc transporter domains	Broad	LT fusion disrupted	May be important for cell–cell contact or cell shape changes	Van Doren *et al.* (2003)
headcase (hdc)	CG15532	Novel cytoplasmic protein	Fusion cells in DB, LTa, and LTp	Extra terminal branches near fusion cells in DB, LTa, and LTp	Represses terminal branching; acts cell nonautonomously	Steneberg *et al.* (1998)

hunchback (hb)	CG9786	Zinc finger transcription factor	Bridge cells	Impaired DT pathfinding and loss of DT fusion	Required for bridge cell viability and expression of guidance cues for DT	Wolf *et al*. (2002)
members only (mbo)	CG6819	Nucleoporin	Upregulated in fusion cells	Disruption in DB fusion	Required for DB fusion; upregulated by Esg	Uv *et al*. (2000)
Notch (N)	CG3936	Transmembrane protein with EGF repeats and cell adhesion function	Upregulated in tip cells	Various fusion defects	Activated Notch represses fusion gene expression including *esg*	Ikeya and Hayashi (1999), Llimargas (1999), Steneberg *et al*. (1999), Chihara and Hayashi (2000)
short stop (shot)	CG18076	Actin and microtubule binding plakin	Ubiquitously expressed	Disrupted fusion	Required for remodeling of initial E-cadherin contact between fusion cells, formation of the associated F-actin structure, and lumen formation	Lee and Kolodziej (2002)
shotgun (shg)	CG3722	DE-cadherin	Upregulated in all fusion cells before fusion	Interrupts all fusion events	Required for initial fusion cell contact and subsequent cell rearrangement during fusion; upregulated by Esg in DB, LTa, and LTp	Tanaka-Matakatsu *et al*. (1996)
wingless (wg) = *wnt1*	CG4889	Wnt-1-family member		Loss or partial loss of branch fusion	Promotes fusion gene expression; ligand for Frizeled signaling pathway	Chihara and Hayashi (2000), Llimargas (2000)

[a]The expression pattern, phenotype, and function described for any gene in this table only refers to its role in branch fusion, as does the chosen reference(s). The phenotype of genes with multiple functions during development may have been concluded from studies using hypomorphic or temperature sensitive alleles, expression of dominant negative alleles, or RNA interference (RNAi).

DB, dorsal branch; DT, dorsal trunk; EGF, epidermal growth factor; FGF, fibroblast growth factor; GB, ganglionic branch; HLH, helix–loop–helix; LT, lateral trunk; LTa, lateral trunk anterior; LTp, lateral trunk posterior; TGF, transforming growth factor.

Table 6 Genes required for terminal branching[a]

Gene	CG number	Product	Expression	Phenotype	Function	References
adrift (aft)	CG5032	Novel nuclear protein	Terminal cells	Misguidance of GB terminal cell into the CNS	*aft* is induced by Bnl; required for GB terminal cell to switch migration substrate from intersegmental to segmental nerve and entry into the CNS	Englund *et al.* (1999)
blistered (bs) = pruned = DSRF	CG3411	Drosophila serum response factor, a MADS domain transcription factor	Terminal cells, just before terminal branching begins	No terminal branch formation	Regulator of terminal branching; forms a transcription complex together with Elk-1; *bs* expression is activated by Bnl signaling	Affolter *et al.* (1994b), Guillemin *et al.* (1996)
inflated (if) = αPS2	CG9623	αPS2-integrin, heterodimerizes with βPS integrin (Mys)	Visceral mesoderm	VB fail to migrate along the visceral mesoderm	Mediates adhesion between VB and visceral mesoderm	Boube *et al.* (2001)
Lamin (lam) = misguided	CG6944	Nuclear lamin	Broad	Terminal branches misguided and sometimes stalled	Component of the nuclear lamina, required for polarized outgrowth of terminal branches	Guillemin *et al.* (2001)
laminin A	CG10236	Component of basal lamina		Gaps in DT	Probable ligand for integrins	Stark *et al.* (1997)
multiple edematous wings (mew) = αPS1	CG1771	αPS1-integrin, heterodimerizes with βPS integrin (Mys)	Visceral branches (stages 11–13)	VB fail to migrate along the visceral mesoderm	Mediates adhesion between VB and visceral mesoderm; *mew* is regulated by the branch-specific Salm, Kni, and Knrl	Boube *et al.* (2001)
myospheroid (mys) = βPS	CG1560	βPS integrin, heterodimerizes with αPS-integrins	Maternal contribution	Similar to *mew*, but more extreme: some VBs detach from mesoderm, gaps in the DT and defects in DB	Mediates adhesion between VB and visceral mesoderm	Boube *et al.* (2001)
roundabout (robo)	CG13521	Slit receptor	From stage 11, in DT at stage 13	Misguidance of GB terminal cell within the CNS	Required in tracheal cells for perceiving the repellent Slit signal, thereby preventing the GB terminal cells from crossing the CNS midline	Englund *et al.* (2002)
scab (scb) = αPS3	CG8095	α-Integrin, forms heterodimer with βPS integrin (Mys)	In tracheal pits and later in a subset of tracheal branches	Gaps in DT	Might be involved in migration and fusion of tracheal cells	Stark *et al.* (1997)
slit (sli)	CG8355	Calcium-binding EGF-like domain, EGF-laminin domain	CNS midline	Misguidance of GB terminal cell within the CNS	Robo-ligand; prevents terminal branch cells in GB from crossing the CNS midline	Englund *et al.* (2002)
synaptobrevin (syb)	CG12210	Vesicular transmembrane protein (v-SNARE activity)		Larval mutant clones produce lumenless terminal branches	Mediates vesicle fusion, essential for lumen growth	Jarecki *et al.* (1999)
unplugged (unpg)	CG1650	HTH transcription factor with a homeobox domain	Ganglionic branches	Misrouted GB	Required for GB entry into the CNS	Chiang *et al.* (1995)

[a]The expression pattern, phenotype, and function described for any gene in this table only refers to its role in terminal branching, as does the chosen reference(s). The phenotype of genes with multiple functions during development may have been concluded from studies using hypomorphic or temperature sensitive alleles, expression of dominant negative alleles, or RNA interference (RNAi).

CNS, central nervous system; DB, dorsal branch; DT, dorsal trunk; EGF, epidermal growth factor; GB, ganglionic branch; HTH, MADS (see www.expasy.org/prosite); VB, visceral branch.

which, in turn, represses fusion cell fate by repressing expression of *esg*. This lateral inhibition mechanism singles out one cell at the tip of each branch, the one with the highest initial expression of *esg* and *Dl*, to become the fusion cell. Esg in turn represses the expression of the terminal branch gene *bs-DSRF*, which thus becomes restricted to the terminal cells. In addition, Esg activates the expression of *headcase* (*hdc*) (**Table 5**), which encodes a cytoplasmic protein acting cell nonautonomously to prevent further stalk cells from undergoing terminal branching (Steneberg *et al.*, 1998). Fusion cells will now form the specialized anastomoses that interconnect the hemisegments to a network (tube type III), whereas terminal cells will continue their journey towards target organs, which they penetrate by the formation of extraordinary capillary tubules (tube type IV).

2.7.4.3.3. Branch fusion The five fusion cells in each hemisegment (see also **Figure 5**) cease branching, and instead contact the corresponding fusion cell in the adjacent or the contralateral metamere (**Table 5**). The two contacting fusion cells then undergo a synchronized process that leads to the formation of an intracellular lumen in each cell and to lumen fusion that connects the two metameres (see Section 2.7.3.4).

The earliest fusion cell-specific protein identified is the zinc finger transcription factor *esg*, which begins to be expressed about 2 h before the initiation of the fusion event (Samakovlis *et al.*, 1996b). The Esg protein is expressed in all five fusion cells, and is required for three of the five fusion events to occur (for the DB, LTa, and LTp), but is redundant for DT fusion, despite its expression in DTa and DTp fusion cells. Because ectopic expression of *esg* in all tracheal cells can suppress terminal branching and promote extra fusion events, Esg appears to act as a key regulator of the fusion cell fate in DB, LTa, and LTp. Indeed, some of the later fusion genes, including *shotgun* (*shg; DE-cadherin*), *members only* (*mbo*), and *hdc*, are not expressed in these fusion cells in *esg* mutants (Samakovlis *et al.*, 1996b; Tanaka-Matakatsu *et al.*, 1996; Steneberg *et al.*, 1998).

The first molecularly recognized step of the fusion event is the deposition of DE-cadherin (DE-cad, Dcad2) at the contact point between the two fusion partners (Tanaka-Matakatsu *et al.*, 1996). The DE-cad protein is an epidermal transmembrane adhesion protein localized at the apical adherence junctions of epithelial cells (Tepass *et al.*, 1996) and is transcriptionally upregulated in fusion cells by Esg. DE-cad interacts with Armadillo (Arm; β-catenin) and Dα-catenin, which, in turn, bind actin filaments linking the plasma membrane to the cytoskeleton. The new deposition of DE-cad at the contact between fusion cells is also associated with Dα-catenin and Filamentous actin (F-actin). In addition, Short stop (Shot), a cytoskeleton associated plakin that interacts both with actin and microtubules, follows the DE-cad distribution throughout the fusion process and is required for DE-cad accumulation at the fusion cell interface (Lee and Kolodziej, 2002). As fusion advances, DE-cad and its associated proteins organize themselves into a line in the proximal–distal orientation. DE-cad then assembles into a circle perpendicular to the presumptive lumen at the interface between the two fusion cells, whereas F-actin remains concentrated in the line, which now spans both fusion cells from one initial lumen bud to the other. Membrane vesicles are expected to accumulate and fuse along this line to facilitate the growth of the intracellular lumen. As the two growing lumina approach the fusion cell interface, the fusion cells contract, displacing their cell bodies cortically, and the F-actin track disassembles to reappear together with microtubular staining at the new adherence ring. The adherence ring expands to the same diameter as that of the connecting primary branches, and lumen fusion between the two fusion cells generates a bicellular anastomosis. Thus, DE-cad redistribution and cytoskeletal modulation are instrumental steps in branch fusion. Reduction of the DE-cad amounts in fusion cells arrests the fusion events at one of the two stages: either before the initial cell contacts are made, or before the expansion of the DE-cad ring, illustrating the requirement for increased amounts of DE-cad at these two stages of the fusion event (Tanaka-Matakatsu *et al.*, 1996). The increasingly detailed description of the fusion process raises many questions on the molecular regulation of the formation and expansion of the DE-cad ring, the polarized growth of the intracellular lumen, and the mechanisms that determine plasma membrane fusion to allow connection of the growing intracellular tubules.

The requirement for increased amounts of DE-cad in the DT fusion cells is not strictly dependent on Esg, since DT fusion is unaffected in *esg* mutants, suggesting that these cells may use a different regulator for branch fusion. Another molecular difference between the fusion cells in DTs and the fusion cells of the DBs and LTs is reflected by the expression of Headcase (Hdc), which occurs in all fusion cells except those of the DT (Steneberg *et al.*, 1998). Whether this difference reflects a distinct mechanism for the actual fusion event in the DT branches, or just a different regulatory mechanism determining fusion cell fate, is not clear.

2.7.4.3.4. Terminal branches Terminal branches are extended unicellular sprouts that target distinct cells and tissues to facilitate gas exchange (see **Table 6**). What triggers the growth of these cells towards different targets and how do single cells form these exquisitely ramified intracellular tubes?

Terminal branch growth selectively requires Blistered (Bs; also called Pruned and DSRF) expression as, in *bs* mutant embryos, terminal cells undergo the initial sprouting from primary branches, but fail to develop the intracellular tube distal to the nucleus (Affolter *et al.*, 1994a; Guillemin *et al.*, 1996). The *bs* gene encodes the *Drosophila* homolog of mammalian serum response factor (SRF) (Montagne *et al.*, 1996), a MADS domain transcription factor. SRF, together with Elk-1, forms part of a transcription complex whose activity is regulated by RTK signaling and the Ras–MAPK pathway (Treisman, 1994). Expression of constitutively active DSRF in tracheal cells induces excessive branch outgrowth, with the terminal branches becoming abnormally extended and branched, and additional terminal branches forming from nearby stalk cells (Guillemin *et al.*, 1996). The molecular targets of DSRF that mediate this unique tube growth remain unknown.

During embryogenesis, terminal branches follow prefixed paths towards a variety of targets. During outgrowth of terminal branches, there is no prominent *bnl* expression in the surrounding tissues. Rather, the code for terminal branch migration appears to be the branches' sensing of tissue- or cell-specific guidance cues that are provided within the immediate migratory environment. Extension of the ganglionic branch terminal cell, for example, is guided by a number of signals that are also followed by neuronal axons (see **Chapters 1.10** and **2.3**). At the CNS entry point, the terminal cell switches its substrate from the intersegmental nerve to follow the segmental nerve to the ventral midline, a process requiring the homeodomain protein Unplugged (Unpg) (Chiang *et al.*, 1995) and the nuclear protein Adrift (Aft) in the terminal cell (Englund *et al.*, 1999). The subsequent branch navigation into the nerve cord is determined by specific cellular contacts made by the terminal cells, and signals emanating from distinct glial cell populations. The CNS provides a rich source of attractant and repellent signals for terminal cell migration, since the single ganglionic branch terminal cell that penetrates this tissue turns at least five times along its journey to the target. Slit signaling is reemployed by the GB terminal cells and, this time, it acts to repel both terminal cells and axons from crossing the midline (Englund *et al.*, 2002).

Another studied example of terminal branch pathfinding is the targeting of the gut, carried out by the terminal cells located at the tip of the visceral branch. α-PS1 integrin is selectively expressed in visceral branch cells and is required for their migration along the visceral mesoderm, which expresses the α-PS2 integrin ligand. Ectopic tracheal expression of PS1 integrin results in misguidance, highlighting again the importance of localized expression of distinct guidance receptors and adhesion molecules in different groups of terminal cells (Boube *et al.*, 2001). How is then such cell- and branch-specific expression achieved? PS1 integrin expression is activated and restricted to visceral branches by Kni, Knrl, and Salm (**Table 2**), which are induced by the early signaling pathways that subdivide the tracheal placode (see Section 2.7.4.2). Aft, alternatively, is expressed in the tip cells of all growing primary branches, and later becomes restricted to terminal cells and is activated by the Bnl signaling pathway (Englund *et al.*, 1999). Thus, at least two independent genetic hierarchies intersect to direct unique combinations of tracheal cell-specific expression of guidance receptors, allowing terminal cells to respond to cues in their immediate environment.

2.7.5. Control of Branch Size

The transport efficiency of tubular organs is dependent on the coordination of tube length and diameter of the branches of the network. In the trachea, air enters into the DT and becomes distributed to gradually narrower branches towards target tissues. Morphometric analysis of the diameter and length of primary branches during embryogenesis indicates that both dimensions are under strict genetic control: branch sizes are invariable from embryo to embryo, expand at certain developmental intervals, and show consistent variations between the different metameres (e.g., the DT diameter becomes gradually narrower in the more anterior metameres) (Beitel and Krasnow, 2000) (see also **Table 7**).

Tube dimensions can be influenced by at least three parameters: cell number, cell size, and cell shape. How are these parameters co-coordinated during tracheogenesis to give rise to distinct tube dimensions within the network? In the following discussion, type I branches are considered, as most studies regarding tube size involve analyses of these branches.

During embryogenesis, the developing dorsal trunk diameter increases three- to fivefold between stages 14 and 16, although the number of DT cells remains constant. In addition, the tube grows by

Table 7 Genes required for correct tube dimensions[a]

Gene	*CG number*	*Product*	*Expression*	*Phenotype*	*Function*	*References*
bulbous (bulb)	49C1-50D1	Not known		Similar to *nrv2*	Tube size control	Beitel and Krasnow (2000)
convoluted (conv)		Not known		Similar to *nrv2*	Tube size control; not required for paracellular diffusion barrier	Beitel and Krasnow (2000), Paul *et al.* (2003)
coracle (cora)	CG11949	Cytoskeleton protein binding	Broad	Same as *nrv2*	Tube size control; septate junction component; required for paracellular diffusion barrier	Paul *et al.* (2003)
cystic (cyst)	II	Not known		Dilations and constrictions in tube diameter, little or no effect on tube length	Tube size control; required for paracellular diffusion barrier	Beitel and Krasnow (2000), Paul *et al.* (2003)
dacapo (dap)	CG1772	Cyclin-dependent protein kinase inhibition activity	Broad	DT branch does not expand to normal diameter	Cell cycle regulator; in *dap* mutants, all cells divide an extra time, but total cell mass is constant	Beitel and Krasnow (2000)
fasciclin 2 (fas2)	CG3665	Cell adhesion protein with immunoglobulin and MHC domain, fibronectin type 3	All tracheal cells until stage 15	Convoluted tracheae with constrictions and dilations	Homophilic cell adhesion molecule localized to the lateral surface of tracheal cells	Hemphala *et al.* (2003)
gliotactin (gli)	CG3903	Serine esterase activity		Similar to *nrv2*	Tube size control; required for paracellular diffusion barrier	Paul *et al.* (2003)
gnarled (gnar)	85D11-F16	Not known		Similar to *nrv2*	Tube size control	Beitel and Krasnow (2000)
grainyhead (grh)	CG5058	Transcription factor Elf-1/NTF-1	All tracheal cells	Convoluted tracheae	Restricts branch elongation; appears to control apical membrane growth; post translationally regulated by Bnl	Hemphala *et al.* (2003)
l(1) tracheae enlarged (l(1)te)	1-0.3			Greatly enlarged main tracheae; PS sometimes nonfunctional		Manning and Krasnow (1993)
l(1) tracheae ramified (l(1)tr)	1-56			Thick main tubes and numerous side branches		Manning and Krasnow (1993)
l(1) tracheae stretched (l(1)trs)	1-8.0			Thin, stretched tracheae		Manning and Krasnow (1993)
megatrachea = pickel (pck)	2A2-B4	Not known		Too long tubes, little or no diameter effects	Tube size control; required for paracellular diffusion barrier	Beitel and Krasnow (2000), Paul *et al.* (2003)
Na pump α subunit (Atpα)	CG5670	α-Subunit of Na^{+}/K^{+} ATPase	All tracheal cells	Convoluted tracheae with constrictions and dilations	Tube size control; required for proper localization of Cora, Fasciclin 3, Nrx and Disc large to septate junctions; required for paracellular diffusion barrier	Hemphala *et al.* (2003), Paul *et al.* (2003)

Continued

Table 7 Continued

Gene	*CG number*	*Product*	*Expression*	*Phenotype*	*Function*	*References*
nervana 2 (nrv2) = ectatic (ecta)	CG9261	β-Subunit of Na^+/K^+ ATPase	Not known, required at placode stage	Convoluted tracheae with constrictions and dilations	Tube size control; required for proper localization of Cora, Fasciclin 3, Nrx, and Disc large to septate junctions; required for paracellular diffusion barrier	Paul *et al.* (2003)
neurexin (nrx)	CG6827	Transmembrane receptor	Broad	Same as *nrv2*	Tube size control; required for paracellular diffusion barrier	Paul *et al.* (2003)
neuroglian (nrg)	CG1634	Immunoglobulin superfamily cell adhesion molecule	Stage 15; posterior spiracles, transiently	Similar to *nrv2*	Tube size control; required for paracellular diffusion barrier	Paul *et al.* (2003)
pebbled (peb) = hindsight	CG12212	Zinc finger transcription factor	All tracheal cells	Collapsed or dilated tubes during expansion phase; subsequent fragmentation may be due to lack of taenidia	Regulates maintenance of the tracheal epithelium and assembly of taenidia; not required for paracellular diffusion barrier	Wilk *et al.* (2000)
sinuous (sinu)	CG10624	Not known		Similar to *nrv2*	Tube size control	Beitel and Krasnow (2000)
stranded-at-second (sas)	CG2507	Plasma membrane protein with fibronectin type III domains	Strongly in trachea at stage 15 and 16	Convoluted tracheae	Localizes at the apical membrane together with Crb	Schonbaum *et al.* (1992), Wodarz *et al.* (1995)
varicose (vari)	39D3-40B1-	Not known		Similar to *nrv2*	Tube size determinant; required for paracellular diffusion barrier	Beitel and Krasnow (2000), Paul *et al.* (2003)

[a]The expression pattern, phenotype, and function described for any gene in this table only refers to its role in tube size control, as does the chosen reference(s). The phenotype of genes with multiple functions during development may have been concluded from studies using hypomorphic or temperature sensitive alleles, expression of dominant negative alleles, or RNA interference (RNAi).

DT, dorsal trunk; MHC (major histocompatibility complex); NTF, neurogenic binding element transcription factor; PS, posterior spiracle.

approximately 20% in length. This observation suggests that the dimensions of type I tubes are not simply set by cell number. Furthermore, genetic manipulation of the number of tracheal cells indicates that cell number does not correlate with changes in tube dimensions (Beitel and Krasnow, 2000). In *cyclin A* mutants, cell division cycle 16 is converted to an endocycle resulting in half the normal number of cells with twice the normal ploidy and size (Sprenger *et al.*, 1997). In these mutants, however, both the diameter and length of the DT are the same as in wild-type embryos. In embryos mutant for *dacapo (dap),* where many cells undergo an extra round of division without proportionate cell growth (Lane *et al.*, 1996), the dorsal trunks do not become larger than in the wild-type. Their length is the same and the diameter is actually smaller. Although these experiments do not disengage total cell mass (number × size) from tube dimensions, they illustrate that if the cell numbers are altered, the cells somehow compensate for this by altering their cell shape to achieve the correct dimensions. Thus, the mechanisms that control tube dimensions in multicellular type I branches are not intrinsically programmed in individual cells, but rather appear to rely on a global control mechanism.

As tracheal branches grow, their luminal surface is kept relatively smooth, whereas the basal surface appears bulky, suggesting that tube diameter may be regulated by adjusting the luminal cell circumferance rather than the basal outer diameter of the cells. Moreover, during width expansion, it is the inner, luminal diameter that increases the most, whereas the outer one increases only a little if at all. According to measurements of the developing Tr2 DT, the inner diameter increases fourfold (from 0.6 to 2.4 μm) from stages 14 to 16 and the tube elongates by 20%, whereas its outer diameter remains constant (approximately 8 μm) during this period (Beitel and Krasnow, 2000). As this can be achieved without significant changes in total cell mass, the expansion may depend entirely on cell shape changes. Thus, at the level of individual cells, three major cellular events appear essential for tube expansion:

1. Growth of tracheal cell membranes, particularly the apical cell membrane, to accommodate the growing luminal surface.
2. Rearrangements along the lateral cell surfaces to decrease the distance between the apical and basal surface.
3. Cytoskeletal alterations necessary to change cell shape.

A number of mutants have been identified that affect tube dimensions without influencing branch patterning. In two of these mutants, *ribbon* (*rib*) Bradley and Andrew, 2001; Shim *et al.*, 2001) (**Table 3**) and *synaptobrevin* (*syb*) (Jarecki *et al.*, 1999) (**Table 6**), tube growth is inhibited; in one, *grainyhead* (*grh*) (Hemphala *et al.*, 2003) (**Table 7**), the tubes become too long; and in the remaining ones, the tubes are both elongated and also form cysts (local dilations and constrictions in diameter) (Beitel and Krasnow, 2000; Hemphala *et al.*, 2003; Paul *et al.*, 2003). Mutations in *ribbon* (see Section 2.7.4.3.1) and *synaptobrevin* (a vesicular transmembrane protein that mediates vesicle fusion), as well as expression of dominant negative *RhoA* (Lee and Kolodziej, 2002) (**Table 3**), impair or prevent lumen formation, but allow branch budding to proceed, suggesting they are required for apical membrane growth, at least during branch extension. The transcription factor Grainyhead (Grh), on the other hand, appears to specifically prevent excess apical (luminal) membrane growth, and its activity restricts branch extension. The *grh* mutants develop elongated and convoluted tubes towards the end of tracheogenesis, and tracheal cells accumulate excess apical membrane. Tracheal overexpression of Grh produces a phenotype reminiscent of *rib* loss of function, with arrests in lumen growth, but only partial inhibition of tracheal cell movements, generating short branches that lack a lumen. As Grh activity is posttranslationally modulated by Bnl, these results suggest a direct function of Bnl in the control of apical membrane growth (Hemphala *et al.*, 2003).

Mutations for *fasciclin2* (*fas2*), *Atpα* (encoding a Na-K ATPase α-subunit), *nervana2* (*nrv2*; encoding an Na/K ATPase β-subunit), *coracle* (*cora*), *neurexin* (*nrx*), *gliotactin* (*gli*), and *neuroglian* (*nrg*) (**Table 7**) cause the tracheal tubes to become convoluted (too long) and display diameter constrictions and dilations along their lengths (Hemphala *et al.*, 2003; Paul *et al.*, 2003). The proteins encoded by these genes all localize to the lateral cell surface of tracheal cells: Cora and Nrx are septate junction components, and Gli and Nrg are needed for the blood–brain barrier formed by septate junctions. Thus, structures or events at the lateral cell surface also appear to be essential for defining or maintaining tube dimensions.

In summary, the analyses of tracheal tube size genes carried out to date confirm the importance of apical cell membrane growth and lateral surface modulations in controlling tube size. However, no fundamental biological principle for the regulated control of tube size has been discovered. How are the subcellular events coordinated within a single cell and, perhaps more importantly, how are these

events synchronized between all cells in the network to produce correct tube dimensions? The mechanisms ensuring coordinated tube growth may rely on long-range signals from extratracheal sources, tracheal cell-communication, or molecules released into the lumen.

2.7.6. Cuticle and Apical Extracellular Matrix

The cuticle is a key structural component of the trachea (**Table 8**). The insect cuticle is composed of fibrils of chitin, a β1-4 linked polymer of *N*-acetyl-D-glucosamine, embedded in a matrix of proteins and lipids (Cohen, 2001) that provides a formidable barrier to the environment. Although the tracheal cuticle is continuous with the epidermal cuticle, its morphology differs as it forms prominent ridges, called the taenidial folds, that project into the lumen (Manning and Krasnow, 1993; Tepass and Hartenstein, 1994). The taenidial folds appear to run a helical course along the luminal surface, and are thought to provide elasticity to the structure of tracheal tubes, which allows them to expand and contract during the movements of the larva.

The tracheal cuticle is composed of morphologically distinct layers. The most apical epicuticle is composed of two electron-dense leaflets and covers the layer of procuticle, which is made by chitin and its accossiated proteins. The structure and thickness of the cuticular layer varies in different branches.

The tracheal cuticular lining is secreted in the late embryo, beginning at stage 15 or 16 (Campos-Ortega and Hartenstein, 1985; Tepass and Hartenstein, 1994). By this stage, a continuous tracheal network has formed, but the tracheal lumen is still filled with liquid and electron-dense filamentous material (**Figure 7**). The cuticle appears as irregularly spaced electron-dense areas along the apical membrane associated with granular material being deposited in the lumen. Within 1–2 h after secretion begins, a cuticular bilayer (presumably corresponding to the inner and outer epicuticle) has formed (**Figure 7**). Taenidial folds become visible and the cuticle is mature by the end of stage 17 (**Figure 7**).

A zinc finger domain transcription factor encoded by the *pebbled* (*peb*, also called *hindsight*) gene (Wilk *et al*., 2000), and an extracellular cell adhesion protein, Pollux (Plx) (Zhang *et al*., 1996) (**Table 8**) are required for the assembly of the taenidia and the organization and attachment of the apical extracellular matrix to the epithelium. The regular patterning of taenidia is generated by an unknown mechanism, which may involve the regular spacing of apical, microvillar-like protrusions of the underlying tracheal epithelium.

The synthesis of the chitin chains, catalyzed by chitin synthases, appears to occur intracellularly. Analysis of the sheep blowfly (*Lucilia cuprina*) chitin synthase suggests an integral membrane protein with the catalytic domain located on the cytosolic face of the plasma membrane (Tellam *et al*., 2000). Thus, the polymers must be extruded across the membrane, perhaps through a pore formed by the 15–20 predicted transmembrane domains of the chitin synthase. Two *Drosophila* genes encoding chitin synthases have been identified (Gagou *et al*., 2002) and at least one of these, *krotzkopf verkehrt* (*kkv*) (Ostrowski *et al*., 2002) (**Table 8**), is expressed in the developing embryonic trachea. Surprisingly, *kkv* begins to be expressed in all tracheal cells already during stage 13, much earlier than the reported cuticle secretion. Perhaps Kkv is produced as a zymogen that is first activated during stage 15; alternatively, chitin secretion starts long before the appearance of a cuticular layer in transmission electron microscopy (TEM) preparations.

The transcription factor Grainy Head (Grh) (**Table 8**), which is expressed in all tracheal cells throughout embryogenesis, also appears to be involved in cuticle formation, since one of its target genes is *dopadecarboxylase* (*ddc*) (**Table 8**), encoding an enzyme that is necessary for hardening and darkening of the cuticle (Bray and Kafatos, 1991). Ddc is expressed late in embryogenesis (stage 17) and is thus involved in the terminal stage of the cuticle synthesis program.

Apart from the apical cuticle, tracheal cells, as well as epidermal cells, secrete an intraluminal matrix, evident from electron microscopy studies (Tepass and Hartenstein, 1994). This appears already at stage 11 and can be seen until late stage 15, when the cuticle becomes evident. The molecular composition or function of this matrix are not known. It could contain chitin and molecules recognized by orphan antibodies (like the 2A12 antigen) that stain the tracheal lumen and the large protein Dumpy, which may form large intraluminal fibrils (Wilkin *et al*., 2000). Such a matrix could provide anchoring for proteins that not only facilitate cross-linking and structural support of the matrix, but also influence the behavior of the underlying tracheal epithelium.

2.7.7. Gas Filling of the Lumen

From the time the tracheal system begins to form until late in embryogenesis, it is filled with liquid and electron-dense material. The liquid initially

Table 8 Genes required for cuticle formation[a]

Gene	*CG number*	*Product*	*Expression*	*Phenotype*	*Function*	*References*
dumpy (dp)	CG15637	Large extracellular matrix protein	In tracheal cells from pit stage to at least stage 12	Structural defect in cuticle; trachea fails to fill with gas	Predicted membrane-anchored fiber that is cross-linked within the cuticle to provide strong anchor for the underlying tissue	Wilkin *et al.* (2000)
grainyhead (grh)	CG5058	Transcription factor Elf-1/NTF-1	All tracheal cells	Thin and flimsy cuticle	Activates *dopadecarboxylate*, which is needed for coloring and hardening of the cuticle	Bray and Kafatos (1991)
krotzkopf verkehrt (kkv)	CG2666	Chitin synthase	In all tracheal cells beginning at stages 11–12		Catalyzes the synthesis of chitin chains, the main component of cuticle	BDGP
Matrix metalloproteinase 1 (Mmp1)	CG4859	Metalloendopeptidase activity	Larval trachea	Larvae exhibit short and sometimes broken DT and other branches; uneven DT diameter	Required for growth of the larval trachea and release of cuticle, may be due to inability of cells to detach from the cuticle	Page-McCaw *et al.* (2003)
pebbled (peb) = hindsight	CG12212	Zinc finger transcription factor	All tracheal cells	Taenidia do not form on the luminal surface of tracheal cells	Regulates assembly of taenidia, may be indirect due to requirement for tracheal epithelium integrity	Wilk *et al.* (2000)
pollux (plx)	CG1093	Extracellular adhesion protein	In primary branches from stage 14	Fluid-congested trachea in 1st instar larvae	Required for contact between tracheal epithelium and extracellular matrix	

[a]The expression pattern, phenotype, and function described for any gene in this table only refers to its role in cuticle formation, as does the chosen reference(s). The phenotype of genes with multiple functions during development may have been concluded from studies using hypomorphic or temperature sensitive alleles, expression of dominant negative alleles, or RNA interference (RNAi).

BDGP, Berkeley *Drosophila* genome project; DT, dorsal trunk.

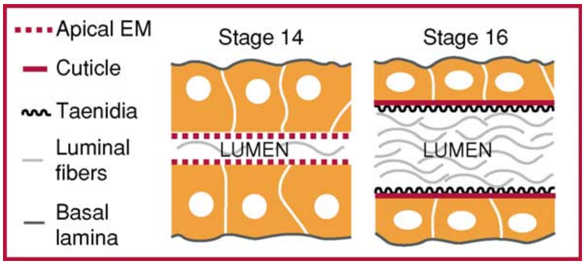

Figure 7 Changes in tube shape and extra cellular components during dorsal trunk development. Drawings of longitudinal sections of the dorsal trunk at stage 14 (left) and stage 16 (right). The dorsal trunk expands about threefold in diameter from stage 14 to stage 16, and is actively secreting apical luminal components during this time period. At stage 14, an apical extracellular matrix (EM) covers the apical cell surface, and filamentous material begins to accumulate in the lumen. At stage 16, a cuticle with the characteristic taenidia is lining the apical cell surface, and the lumen is filled with fibrillar material. This becomes cleared during stage 17 before the larva hatches. A basal lamina is associated with the outer cell surface throughout tracheogenesis.

derives from fluid in the perivitelline space that surrounds the embryo. About 2 h before hatching, this liquid is absorbed and the tracheal system gradually fills with gas. Gas filling occurs before the spiracles open, and can occur when the egg is surrounded by oil, indicating that the gas must derive from nearby tissue or from liquid in the trachea (Manning and Krasnow, 1993).

Lumen clearance appears to be an active process mediated by the tracheal epithelium, where the liquid is absorbed into the tissues. In mammals, the conversion from liquid- to air-filled tubules in the lung occurs at birth, when the epithelium actively absorbs salt and hence liquid. This process requires the activity of the epithelial Na^+ channel (ENaC), which contributes to salt and liquid absorption. Liu *et al*. (2003a) showed that related *Drosophila* degenerin DEG/ENaC family members are expressed in the embryonic tracheal system. These have been termed Pickpocket (Ppk) 4, –7, –10, –11, –12, –14, –19, and –28 (**Table 9**), and may function to clear liquid and generate an air-filled tubule system. By *in situ* hybridization, their expression appeared in late-stage embryos after tracheal tube formation, with individual *ppk* genes showing distinct temporal and branch-specific expression patterns. Moreover, when RNA interference was used to silence two of these genes, *ppk4* and *ppk11*, the larvae failed to clear tracheal liquid. Thus, the related *Drosophila* Ppk proteins and mammalian ENaC proteins may share a physiological function in clearing liquid from the airways.

A second gene that is required for lumen clearance and gas filling without affecting the overall development of the tracheal network is *congested-like trachea (colt)* (Hartenstein *et al*., 1997) (**Table 9**). It encodes a putative mitochondrial carrier protein but its function in the process remains unknown.

2.7.8. Larval Growth of the Tracheal System

The stereotyped migration of terminal branches ensures air supply to the different tissues of newly hatched larvae. Larval life, however, is a period of extensive organismal growth with a continuous need for enhanced oxygen supply. This is accommodated both by the size expansion of the existing tracheal tubes (Beitel and Krasnow, 2000) and by terminal branch ramification.

2.7.8.1. Growth in Branch Dimensions

As new terminal branches ramify during insect larval growth, the pre-existing proximal branches expand in diameter, so that their cross-sectional area is roughly the same as the combined cross-sectional area of its more distal branches, in order to maintain sufficient gas flow. The cellular basis for larval branch expansion in *Drosophila* depends on enlargements in tracheal cell size, rather than cell division, while in other insects it may employ both cell growth and division (Manning and Krasnow, 1993).

In 1958, Locke showed that an increase in lumen diameter of proximal branches in *Rhodnius* is observed, when the larva is subjected to limited oxygen conditions. The signal to increase luminal size is unknown, but Locke's studies suggested that it derives from the terminal branches and propagates retrograde toward the larger, more proximal branches, without diversion to side-branches. In *Drosophila*, the dorsal trunk diameter expands 40-fold from embryonic stage 12 until late third instar larvae, but larval tube growth (at least in the case of DT and LT) occurs within discrete periods (Beitel and Krasnow, 2000). The diameters are constant throughout the first larval period, but increase abruptly at each larval molt, when the cuticle is shed and replaced by the newly deposited cuticle. Growth in tube length, however, steadily increases throughout larval life and oxygen physiology does not appear to influence tube expansion. A comparison of the DT and TC branch size between larvae reared in normal (21%) or low (5%) oxygen (a condition that stimulates terminal branching) showed that tube diameters were not significantly changed by hypoxia, and there was only a small reduction in DT and TC length, which paralleled the reduction in overall body size seen under the hypoxic condition. The

Table 10 Genes required for hypoxic response[a]

Gene	*CG number*	*Product*	*Expression*	*Phenotype*	*Function*	*References*
branchless (bnl)	CG4608	Homolog of mammalian FGF	In tracheal target tissues	In hypermorphs, hypoxic tissues fail to attract tracheal branches	Induced by hypoxia to induce and attract new capillaries	Jarecki *et al.* (1999)
breathless (btl)	CG6714	Homolog of FGF receptor, a receptor tyrosine kinase		Dominant negative Btl inhibits terminal branching	Receptor for Bnl	Jarecki *et al.* (1999)
HIF prolyl hydroxylase (Hph)	CG1114	Prolyl hydroxylase	Ubiquitous, upregulated in hypoxia during embryogenesis	Embryonic Sima protein stabilized in normoxia, with subsequent activation of hypoxic reporter genes	In normoxia Hph modifies Sima so it is recognized by E3 ubiquitin–ligase complex, leading to Sima degradation by the proteasome	Bruick and McKnight (2001), Lavista-Llanos *et al.* (2002)
similar (sima) = HIF-1α	CG7951	bHLH-PAS domain, α-subunit of HIF transcription factor	In hypoxia, strong expression in trachea at stages 15–16, but not in normoxia		Regulator of hypoxic response; under hypoxic conditions, Sima protein levels are increased and Sima translocates to the nucleus to activate hypoxia-responsive genes	Lavista-Llanos *et al.* (2002)
tango (tgo) = dARNT = HIF-1β	CG11987	bHLH-PAS domain, β-subunit of HIF transcription factor	Broadly expressed	Fails to induce hypoxic reporter gene expression	Regulator of hypoxic response	Lavista-Llanos *et al.* (2002)
von Hippel–Lindau (Vhl)	CG13221	vHL domain	DT at stage 15, then in smaller branches	DT breaks and ectopic branching	Part of E3 ubiquitin–ligase complex involved in Sima degradation; appears to halt cell movements at branch tips	Adryan *et al.* (2000), Aso *et al.* (2000)

[a]The expression pattern, phenotype, and function described for any gene in this table only refers to its role in hypoxia, as does the chosen reference(s). The phenotype of genes with multiple functions during development may have been concluded from studies using hypomorphic or temperature sensitive alleles, expression of dominant negative alleles, or RNA interference (RNAi).

bHLH, basic helix–loop–helix; DT, dorsal trunk; FGF, fibroblast growth factor; HIF, hypoxia induced factor.

conclusion from these experiments was that differences in oxygen physiology and general growth control have little or no effect on tube diameter in *Drosophila*, but can influence tube length, and that tube diameter and tube length may be independently regulated (Beitel and Krasnow, 2000).

2.7.8.2. Formation of New Capillaries

Each terminal branch may ramify several times during the larval period, generating complex trees of tracheoles that infiltrate the target tissue (**Figure 4c**). Such sprouting and growth of larval tracheoles is regulated by local oxygen demand in body cells, and the molecular components involved in the activation of hypoxic responses appears to be conserved between *C. elegans*, *Drosophila*, and mammals. Cells that experience hypoxia turn on the expression of Bnl, and nearby terminal branches respond by growing new tubes towards the Bnl source, where they arborize (Jarecki *et al.*, 1999). The molecular mechanism of activation of Bnl in hypoxic tissues is not yet understood. It may involve hypoxia response elements resembling the DNA binding sites of the mammalian hypoxia-inducible factor (HIF-1) in the *bnl* promoter (Nagao *et al.*, 1996). Such reporter elements can be activated in *Drosophila* by the endogenous transcription factors Similar (Sima, a HIF-α homolog) and Tango (a HIF-β homolog) (**Table 10**). Interestingly, Sima appears to be regulated posttranslationally by a prolyl hydroxylase protein encoded by the *CG1114* gene (Lavista-Llanos *et al.*, 2002) (**Table 10**).

Thus, terminal branches are guided both by developmental cues and physiological needs. Being formed by single cells, they undeniably provide a powerful system to aid the dissection of cellular mechanisms governing pathfinding and intracellular tube growth.

2.7.9. Concluding Remarks

The genetic analysis of larval tracheal development in *Drosophila* has established many of the basic principles of branch patterning and tube growth that generate a highly elaborate epithelial tubular network. Cell migration, changes in cell shape, and selective growth of apical membrane are essential events in the directed tracheal tube growth toward its targets. These processes are employed in four different schemes of tube formation to accommodate optimal airflow, branch fusion, and tissue targeting for direct gas exchange.

Many of the molecules involved in tracheal development are common to all aspects of epithelial organ morphogenesis, and the question becomes defined to the regulatory aspects of these molecules during tube formation. The development of new methodologies for visualizing subcellular structures and the continuously expanding possibilities for genetic analysis ensure that the ongoing dissection of tracheal development will provide significant contributions to the molecular understanding of luminal growth control, branch fusion, and responses to signals from the developing surrounding tissues.

An important aspect of tracheal development that remains almost completely unexplored at the molecular level is the formation of the adult respiratory system (review: Manning and Krasnow, 1993). Cell division plays an important role in the formation and growth of the pupal and adult trachea, and the study of their development is certainly going to unravel new principles in the control of branching morphogenesis. Another key issue that is only beginning to be addressed at the molecular level is how the physiology of respiration may control capillary growth and retraction. The pioneering studies by Wigglesworth and colleagues on tracheal remodeling in *Rhodnius prolixus* exposed to hypoxia or hyperoxia have shown a fascinating interplay between the air-deprived cells and the adjacent trachea. Thus, it will be of great interest to identify the molecular mechanisms underlying such dynamic cell behavior. The wealth of genetic and molecular information emerging from the analysis of embryonic tracheal development will hopefully aid the molecular dissection of these processes in *Drosophila* and other insects.

Acknowledgments

The authors are indebted to Anna Tonning for her great contribution to the tables. They thank Daniel Mattson and Pär Steneberg for allowing the use of unpublished images and help with the figures, and Johanna Hemphälä for comments on the article.

2.8 Development of the Malpighian Tubules in Insects

B Denholm and H Skaer, University of Cambridge, Cambridge, UK

2.8.1. Introduction

The Malpighian tubules were first described by the seventeenth-century anatomist Marcello Malpighi in his 1669 monograph on the silkworm, *Bombyx mori* (Malpighi, 1669). He was the first to link anatomical description of these organs with their physiological function, namely excretion. In most insects, the Malpighian tubules represent the chief excretory organ and, as such, are an important site for regulating physiological homeostasis. To this end, they may be called upon to perform a number of functions: (1) removal of the end products of metabolism; (2) removal of excess salts; (3) elimination of toxins; and (4) maintenance of the ionic and osmotic properties of the blood.

The work of Wigglesworth and Ramsay during the course of the last century established the Malpighian tubules as a model for the study of transporting epithelia (Wigglesworth, 1939; Ramsay, 1954, 1955, 1958). These early works focused on the tubules of the blood-sucking hemipteran *Rhodnius prolixus* and the stick insect *Dixippus morosus*, both large species with experimentally tractable tubules. It was here that the foundations of experimental insect physiology were established. This tradition continued throughout the latter part of the twentieth century and, with the development of an isolated tubule assay to facilitate study in other insect species, a relatively comprehensive description of Malpighian tubule physiology across several species was established.

In parallel with these physiological analyses, Malpighian tubules from various species have been examined both at the morphological and ultrastructural levels (Wigglesworth and Salpeter, 1962; Berridge and Oschman, 1972; Wessing and Eichelberg, 1978; Skaer *et al.*, 1987). Studies such as these reveal that

despite their varied morphology, insect tubules conform to a basic design: polarized epithelia tubes with regions specialized for fluid secretion, toxin clearance, and reabsorption of solutes and water. In some cases, these studies, in combination with physiological analysis, allow direct correlation between structure and physiological function (Skaer *et al.*, 1990; O'Donnell *et al.*, 1998).

In the last decade, the subject of tubule development has come into focus. This area of study has been dominated by a single insect species, namely *Drosophila melanogaster.* The use of *Drosophila* has been fruitful in revealing both cellular and molecular aspects of tubule development. These findings provide a reference point not only for studies of tubules in other species but for questions relating to the development of transporting epithelia and differentiated cell function in general. Recently, the coupling of traditional physiological assays (Dow *et al.*, 1994) with the power of *Drosophila* genetics has allowed a more detailed molecular description of physiological function to emerge.

The focus of this chapter is the development of insect Malpighian tubules, with particular emphasis given to a molecular description of development. In light of this, much of what follows is dominated by description of tubule development in *Drosophila*, because it is in this species that a comprehensive dissection of development has been performed.

The development of *Drosophila* tubules can be viewed as occurring in several, relatively discrete, steps: (1) the allocation of tubule primordial cells; (2) cell division of these primordial cells; (3) differentiation of specific cell types; (4) cell rearrangement and morphogenesis; (5) recruitment of cells to the tubules; and (6) the onset of physiological competence (**Figure 1**). These steps are dealt with separately below (see Sections 2.8.3 to 2.8.8). Despite the amount of space given over to descriptions of *Drosophila* development, comparisons with other insect systems will be made where data exist. A comprehensive description of insect Malpighian tubule physiology is not included here as this has been reviewed recently elsewhere (Dow and Davies, 2001). A brief summary of tubule physiology is provided below (see Section 2.8.2.1).

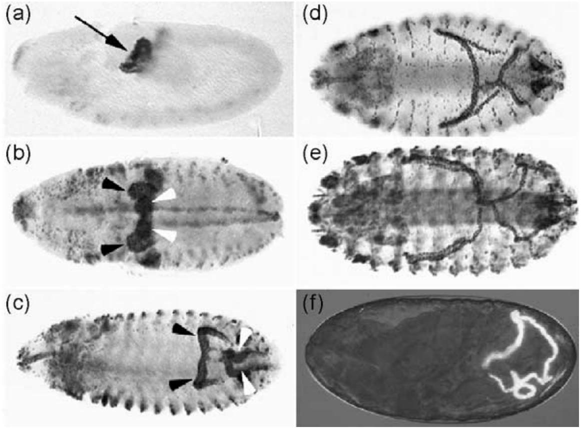

Figure 1 Embryonic development of *Drosophila* Malpighian tubules. (a–e) Embryos stained with an antibody against the transcription factor Cut, which labels tubule cells throughout embryonic development. (a) The tubules evert from the hindgut when the germband is fully extended at stage 9 (arrow). (b–d) The tubules grow by cell division during stages 9–13, as the germband retracts (b and c) and thereafter by elongation, through convergent-extension movements (d). (e) At stage 16, the tubules have adopted their stereotypical arrangement within the embryonic cavity. (f) At stage 17 the first signs of physiological activity can be seen as uric acid is deposited into the posterior tubules (revealed as a bright deposit under polarized light). Embryos are shown in lateral view (a) and in dorsal view (b–f) with anterior at left and posterior at right. Black arrowhead, anterior tubule; white arrowhead, posterior tubule.

2.8.2. Malpighian Tubule Form and Function

2.8.2.1. Insect Malpighian Tubule Function and Physiology

The function of an excretory system is to remove harmful or unnecessary substances from the body. In most animals this is achieved in the same way. First, a relatively nonselective filtration barrier filters the extracellular fluid to hold back cells and large molecules such as proteins, but permits the passage of smaller molecules, including harmful substances. Second, the filtrate passes along the lumen of a tube where retrieval of useful substances takes place and further transport of harmful substances into the lumen occurs. The Malpighian tubules are the primary organ of excretion in insects and as such conform to this fundamental design (Maddrell, 1981). Primary urine production results from transport across distal tubule cells and the resulting solvent drag increases flow into the lumen through the paracellular spaces between the tubule cells. This forms the filtration barrier through which novel toxins are cleared from the hemolymph. Importantly, this barrier is relatively nonselective allowing the passage of toxic and unwanted substances in addition to essential substances. The filtrate is then modified by active reabsorption of essential compounds and additional active transport of toxic molecules into the lumen by specific transporters.

Central to the function of the tubules is an apical vacuolar-type H^+-ATPase (Davies *et al.*, 1996; review: Dow and Davies, 2001) (**Figure 2**). This

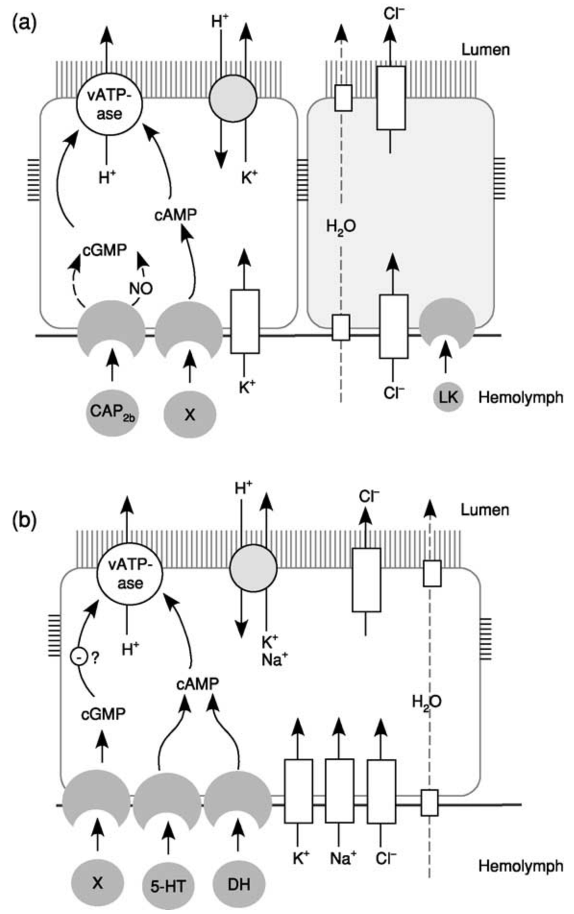

Figure 2 The transport processes involved in tubule function. Ion transport is driven by the activity of an H^+-transporting vacuolar-ATPase (V-ATPase) situated on the luminal membrane. The V-ATPase, coupled with a cation/H^+ antiporter, constitutes a cation pump that transports sodium ions, potassium ions, or both from the cytoplasm into the tubule lumen. Chloride ions move into the lumen down an electrochemical gradient through chloride-permeable channels. The rate of entry into the cell, from the hemolymph, of sodium, potassium, and chloride ions, through channels and transporters, varies between insect species and depends on the state of stimulation of the tubule. (a) In *Drosophila*, cation transport occurs across the principal cells (PCs, left) whereas chloride ion movement is across the stellate cells (StCs, right). (b) In *Rhodnius* only one secretory cell type exists, through which both cation and anion movements take place. 5-HT, 5-hydroxy tryptamine; CAP2b, cardioacceleratory peptide 2b; DH, diuretic hormone; LK, leukokinin; NO, nitric oxide. The apical cell surface is enriched with microvilli (parallel lines in lumen). Intercellular junctions are shown as cross-hatching between the cells. X indicates as yet unknown agonist(s) that stimulate the elevation of intracellular cyclic AMP levels in *Drosophila* and cyclic GMP in *Rhodnius*.

pump maintains a proton gradient across the apical membrane that ultimately drives the movement of alkaline cations from cell to lumen through apical Na^+/H^+ and/or K^+/H^+ exchangers (see **Chapter 5.1**). The pump also establishes a favorable electrical gradient for the movement of chloride ions from cell to lumen, largely by transcellular transport via chloride channels (see below). Water movement is largely a secondary consequence of active ion transport, the two processes probably being coupled by osmosis. There is some evidence in *Drosophila* that water movement is additionally facilitated by water channels of the aquaporin family (Dow *et al*., 1995) (**Figure 2**). The control of fluid transport in the tubules in response to environmental stimuli is regulated by a number of second messenger pathways including cAMP, cGMP, nitric oxide, and calcium (review: Dow and Davies, 2001). In some species, cation and anion transport occur at largely separable loci within the tubule. In *Drosophila*, cation transport occurs across the apical membrane of principal cells, whereas anion flow is through the stellate cells (O'Donnell *et al*., 1996, 1998). In addition, there is evidence to suggest that transcelluar movement of water via aquaporin water channels in *Drosophila* may also occur specifically through stellate cells (Dow *et al*., 1995, 1998). In contrast, the tubules of *Rhodnius* have only one secretory cell type, through which both cation and anion movement occurs (**Figure 2**).

2.8.2.2. Insect Tubule Anatomy

The general anatomy and cellular architecture of insect Malpighian tubules share a number of common features. They are usually simple tubular structures made up of a single layer of epithelial cells surrounding a lumen. They open into the hindgut, into which excretory products are expelled. Most tubule cells possess the typical attributes of a transporting epithelium such as a distinct apico-basal polarity, with the apical surface facing the lumen, elaboration of membrane surfaces to form microvilli and enrichment with organelles such as mitochondria (**Figure 3**).

Despite these fundamental similarities there is considerable variation in the form and number of Malpighian tubules across the insect class (**Figure 4**). Generally, the Malpighian tubules lie freely in the hemolymph of the body cavity (**Figure 4a**) but, in some species, regions of the tubule can form intimate contacts with parts of the gut. Some tenthredinid and lepidopteran larvae and many beetles have a cryptonephridial arrangement, where the distal ends of the tubules associate with the rectum, with which they are enclosed in a common membrane and muscular sheath (Ishimori, 1924) (**Figure 4b**). Such arrangements permit maximum water reabsorption and are often associated with species living in particularly dry environments. Some species possess tubules of more than one

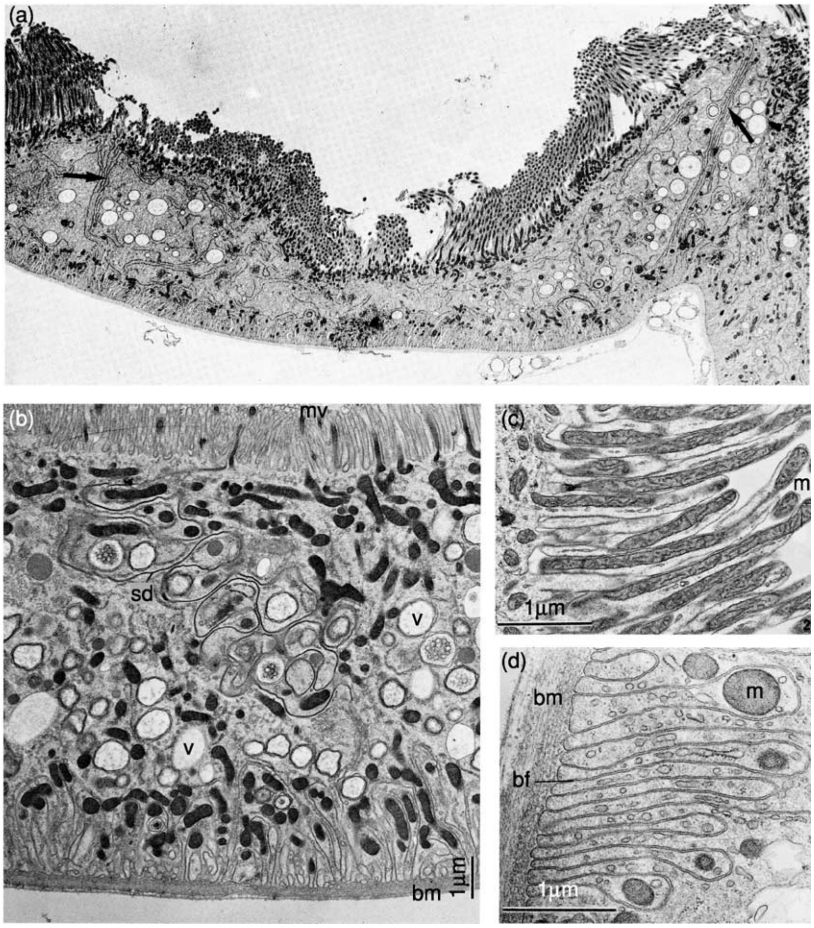

Figure 3 The secretery region of the Malpighian tubules of adult *Rhodnius prolixus* (a) and *Periplaneta americana* (b–d). The Malpighian tubules are a single cell-layered epithelium with pronounced apicobasal polarity. In both species, the apical membrane is densely populated with microvilli, and the basal membrane forms convoluted infoldings that can clearly be seen at higher magnification (c, microvilli and d, basal infoldings). Arrows in (a) show intercellular junctions; bf, basal folds; bm, basement membrane; m, mitochondrion; mv, microvilli; sd, septate desmosome; v, vacuole. Scale bar in (b–d) = 1 μm. (Reproduced with permission from Berridge, M.J., Oschman, J.L., **1972**. Transporting Epithelia. Academic Press, London.)

type; for example, in the curculionid *Apion*, there are four long tubules and two short tubules forming globular or flask-shaped glands (Holmgren, 1902). Branched tubules are also found sometimes. For example, in chrysomelids such as *Galerucella*, there are two types of tubule, two short unbranched anterior tubules, and four elongated posterior tubules, which unite on each side into a common stem, and branch on the surface of the rectum (Heymons and Lühmann, 1933) (**Figure 4c**). Finally, in some species, the tubules anastomose with each other to form closed loops, as in *Gnaptor*, *Tipula*, and cecidomyids (Gorka, 1914; Bodenheimer, 1924) or form crossings through which the lumen is continuous, as in some Homoptera (Licent, 1912). The tubules can also vary considerably in number, with some Hemiptera and various coccids possessing only two, while the locust *Schistocerca gregaria* has in excess of 200 (**Figure 4d**).

The variety in form observed in tubules of different species represents different ways of achieving adequate excretory capacity. For example, the tubules of species with high numbers of tubules are often short, whereas those from species with few tubules are often long and convoluted. As insects grow, there is a concomitant requirement for an increase in excretory capacity, and insects vary in the way that they cope with this challenge. In some species, increased capacity is achieved by cell growth, resulting from endoreplication of tubule cell DNA, without further cell division, whereas other species produce additional tubules throughout life so that, depending on the species, the adult number is from 50 to 250 (**Figure 4d**). Of the groups studied to date, Diptera, Lepidoptera, Coleoptera, and Hemiptera adopt the first strategy, while Orthoptera, Dictyoptera, and Hymenoptera adopt the second, though some ants and bees appear to

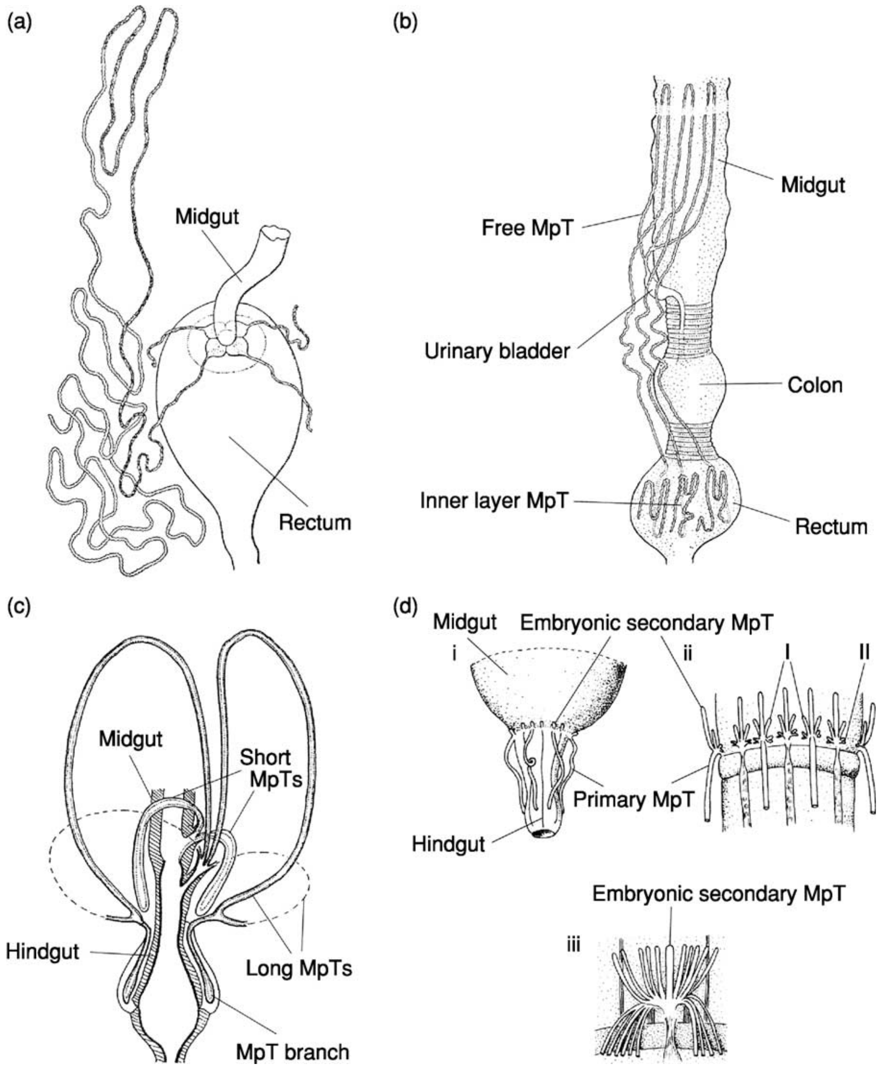

Figure 4 Diversity of Malpighian tubule form in insects. (a) *Rhodnius prolixus* has four free floating Malpighian tubules (only one tubule is shown in its entirety). (b) The Malpighian tubules of *Vanessa urticae* have a cryptonephridial arrangement, where the distal ends are intimately associated with the rectum, buried beneath a membrane and muscular sheath. (c) *Galerucella* has six Malpighian tubules, two short unbranched and four long branched tubules. The long tubules unite on each side into a common stem which then splits into three terminal branches lying in a chamber on the surface of the rectum. (d) The Malpighian tubules of (i) embryonic, (ii) second instar, and (iii) adult *Schistocerca* (a single cluster is shown), illustrating the continued production of new tubules during postembryonic development (I, first instar secondary tubules; II, second instar secondary tubules). ((a–c) Reproduced from Wigglesworth, V.B., **1939**. The Principles of Insect Physiology. Methuen, London; and (d) reproduced with permission from Savage, A.A., **1956**. The development of the Malpighian tubules of *Schistocerca gregaria* (Orthoptera). *Q. J. Microsc. Soc. 97*, 599–615.)

adopt both, retaining four tubules through embryonic and larval life but replacing them with large numbers of tubules (over 50) in the adult (review: Wigglesworth, 1939).

2.8.2.3. The Anatomy and Function of *Drosophila* Malpighian Tubules

In *Drosophila*, there are four Malpighian tubules, a longer anterior and a shorter posterior pair (Figure 5). The tubules contain two major cell types with separate developmental origins – the principal cells (PCs) and the stellate cells (StCs) (see Section 2.8.7). The anterior tubules each contain 144 ± 10 PCs and 33 ± 0.4 StCs, whereas the posterior tubules each contain 103 ± 8 PCs and 22 ± 0.4 StCs (Janning *et al.*, 1986; Skaer and Martinez-Arias, 1992; Sozen *et al.*, 1997). Each tubule pair is joined by a common ureter that enters the intestine at the junction between the hindgut and midgut. The tubules float freely in hemolymph of the body cavity.

At the ultrastructural level, all cells of the tubule have a polarized architecture. The basal region of the cell faces the hemolymph, with the membrane in this region containing numerous infoldings of

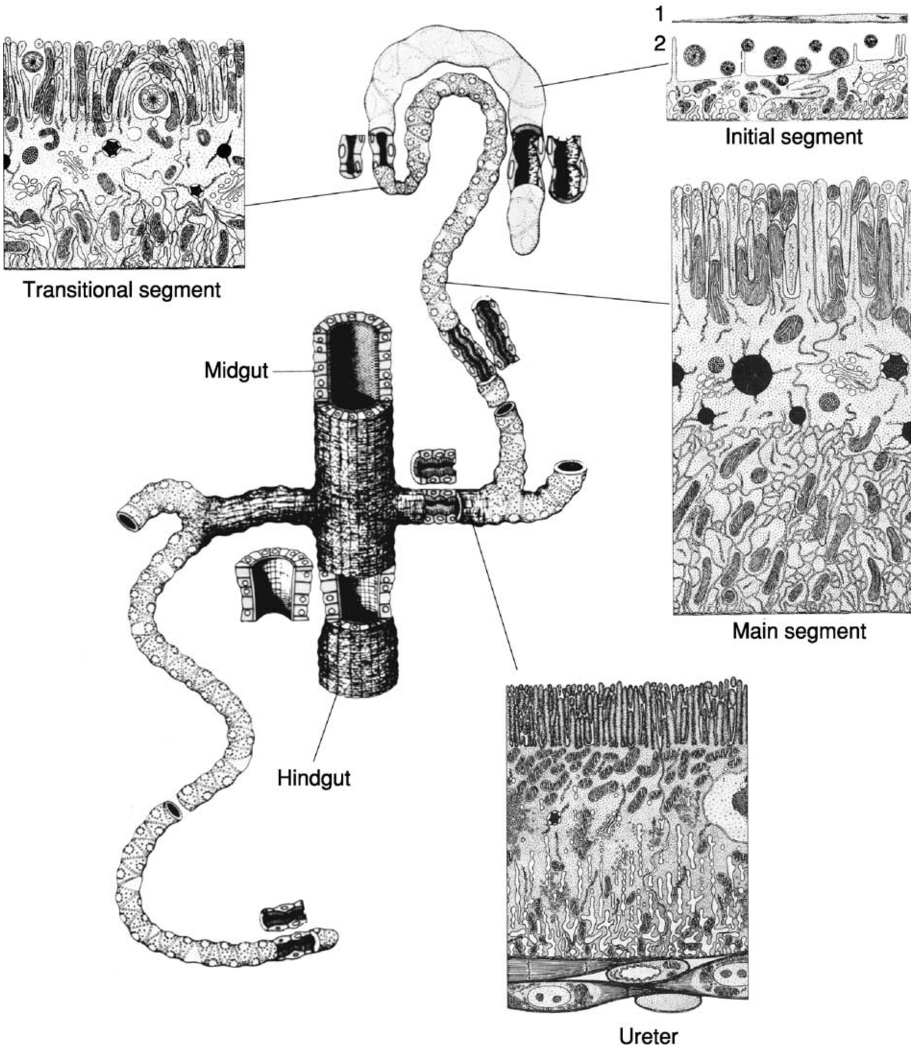

Figure 5 Representation of the Malpighian tubules of *Drosophila melanogaster*. *Drosophila* has four tubules, a longer anterior and shorter posterior pair (one tubule of each pair is depicted). Each tubule can be divided into four distinct regions based on proximodistal differences in cell structure: initial, transitional and main segments and the ureter. The principal cells (PCs) in the initial segment (2) are flattened; they have numerous basal infoldings and possess sparse, short microvilli. The more distally located cells often contain vesicles. The stellate cells (StCs) in the initial segment (1) are also flattened, but unlike the PCs (2), they do not have microvilli or basal infoldings, nor do they contain vesicles. The lumen in this region of the tubule is characteristically filled with many spherical concretions. The cells of the transitional segment are similar to those of the main segment but the microvilli often form arched structures. In the main segment, the PCs have complex basal infoldings and a dense brush border formed by long micovilli. Storage vacuoles are also present in the PCs, but not StCs. The StCs in the main segment are smaller and flatter, and their microvilli are shorter than the PCs. In addition, the StC luminal surface is far smaller than that of the PCs. The cells of the distal ureter are similar to those of the main segment. Proximally, the ureteric cells become more midgut-like, with fewer but wider basal infoldings that penetrate deep within the cell and are ensheathed in visceral mesoderm and invested with tracheoles. (From Wessing, A., Eichelberg, D., **1978**. Malpighian tubules, rectal papillae and excretion. In: Ashburner, M., Wright, T.R.F. (Eds.), The Genetics and Biology of *Drosophila*, vol. 2c. Academic Press, London, pp. 1–42.)

various depths. The apical side of the cell faces the tubule lumen and possesses microvilli, the density and size of which vary, depending upon the proximodistal position of the cell along the tubule length. Mitochondria are enriched both basally, between the infoldings, and in the apical region at the base of the microvilli, into which they often penetrate. The nucleus and other organelles, such as the Golgi apparatus, endoplasmic reticulum, as well multivesicular bodies, are generally found in an intermediate region of the cell (Wessing and Eichelberg, 1978) (**Figure 5**). The cells of the mature tubules are bound by septate junctions but not *zonulae adherentes*, which are present during early development but are then disassembled towards the end of embryogenesis (Tepass and Hartenstein, 1994).

Differences in cell structure exist between the cells along the proximodistal axis of the tubule (Wessing and Eichelberg, 1978). In the anterior tubule, four structurally defined domains have been described: an initial segment at the distal end of the tubule, a short transitional segment, a main segment and a proximal segment (**Figure 5**). This structural classification has been validated by a more recent molecular analysis. Sozen *et al.* (1997) used an enhancer trap technique to reveal patterns of gene expression in the tubules of adult flies. This method showed that some genes are differentially expressed in the tubules, and that these expression domains often correspond to those regions defined by structural criteria. Furthermore, this technique uncovered previously unidentified tubule domains. For example, some enhancer trap lines revealed differences in gene expression between morphologically indistinguishable PCs, suggesting that, although superficially identical, they perform different functions.

Proximodistal differences along the tubule reflect differences in the physiological function of the cells. Primary urine is secreted into the distal region of the tubule (initial and transitional segments), where the epithelium is relatively leaky and, as it flows down the tubule, it is modified by selective reabsorbtion and further inward transport. Modification of the primary urine takes place principally in the main segment, where the apical membrane is decorated with many microvilli to maximize surface area. In this region, useful molecules, such as glucose, are selectively reabsorbed and toxic or unwanted substances are transported into the lumen.

2.8.3. Allocation of Tubule Primordial Cells

2.8.3.1. Origin of the Posterior Gut

Fate mapping experiments (Hartenstein *et al.*, 1985) have shown that the posterior gut arises from two neighboring anlagen: the endodermal posterior midgut anlage and the ectodermal proctodeum that will subsequently give rise to both the hindgut and Malpighian tubules. The posterior gut primordia are specified by the activation of the maternally supplied Torso receptor tyrosine kinase at the posterior of the embryo (St. Johnston and Nüsslein-Volhard, 1992). Signaling through this receptor results in the transcriptional activation, in overlapping posterior caps, of two zygotic transcription factors encoded by *tailless* (*tll*) and *huckebein* (*hkb*) (Weigel *et al.*, 1990). The *hkb* gene is expressed in a smaller, more posterior domain than *tll* and establishes the posterior border of the proctodeal ring (Brönner *et al.*, 1994). The Tll protein acts to establish the proctodeal ring by activating the expression of *brachyentron* (*byn*), *forkhead* (*fkh*), *bowel* (*bowl*), and *wingless* (*wg*) (Mahoney and Lengyel, 1987; Pignoni *et al.*, 1990; Weigel *et al.*, 1990; Kispert *et al.*, 1994; Diaz *et al.*, 1996; Singer *et al.*, 1996; Wang and Coulter, 1996; Wu and Lengyel, 1998). Forkhead in turn activates the expression of the zinc-finger transcription factor Krüppel (Kr) which, like Fkh, is expressed as a cap over the posterior pole of the blastoderm embryo and subsequently in the amnioproctodeal invagination during gastrulation and germband extension (Knipple *et al.*, 1985; Gaul and Jäckle, 1987; Gaul and Weigel, 1990). In addition to these fators, *caudal* (*cad*), which encodes a homeodomain transcription factor, is required for normal posterior gut development (Wu and Lengyel, 1998). The *cad* gene is expressed both maternally in a posterior to anterior gradient and, subsequently, zygotically in a stripe of cells that corresponds to the anlagen of the hindgut and the anal pads (Wu and Lengyel, 1998). In the absence of *cad* expression, terminal expression of *wg* and *fkh* is either abolished or diminished, leading to misspecification and subsequent death of the hindgut primordium (Wu and Lengyel, 1998).

2.8.3.2. Specification of the Tubules: Signaling between Gut Compartments

The tubules originate within the ectodermally derived hindgut primordium in a region adjacent to the midgut anlage (Hartenstein *et al.*, 1985). During gastrulation, the posterior gut primordia invaginate and come to lie internally within the embryo. Specification of tubule fate is first evident soon after gastrulation is complete, during early stage 9 at 4.5 h after egg laying (AEL), when *Krüppel* (*Kr*) refines from a broad domain of cells to a narrower stripe of cells that will form the tubules (see Section 2.8.3.3) (Gaul *et al.*, 1987; Gaul and Jäckle, 1987). The *fkh* gene continues to be expressed throughout the gut, indicating that other factors must regulate *Kr* after cellular blastoderm to restrict its expression. Fate mapping (Hartenstein *et al.*, 1985) reveals that tubule cells are not allocated until after cellular blastoderm, and therefore cell specification must take place some time between the onset of gastrulation and the point at which *Kr* expression refines.

Although the tubules arise from the ectodermal primordium shared with the hindgut, juxtaposition between this tissue and the endodermally derived midgut is necessary for tubule specification. If the midgut is ablated genetically in embryos

doubly mutant for *huckebein* (*hkb*) and *serpent* (*srp*), two genes required for midgut development, tubule cells are never allocated but instead, like cells in the midgut domain, become transformed into hindgut (Ainsworth *et al*., 2000; Ainsworth *et al*., unpublished data). These results are consistent with a hypothesis in which an instructive signal emanating from the midgut is required to specify tubule fate in the shared hindgut/Malpighian tubule primordium. In the absence of the midgut, and therefore the hypothesized signal, tubule fate is not specified and the transformed tissue follows a hindgut fate. The nature of this possible signal or signals is not yet known. Interestingly, a deficiency screen uncovering approximately 70% of the whole genome did not reveal any loci in which tubule specification failed completely (Harbecke and Lengyel, 1995). It is therefore possible that multiple signals acting either additively or redundantly are required for tubule fate specification.

In addition to this putative inductive signal(s) emanating from the midgut, signaling through the Wnt pathway is required at this early stage for the normal specification of tubule cells. Attenuation of either *wg*, or the pathway activators *armadillo* (*arm*; encoding the *Drosophila* β-catenin) and *dishevelled* (*dsh*) leads to a reduction in the number of tubule cells specified. In contrast, loss of the pathway inhibitors *naked* (*nkd*) or *zeste-white3* (*zw-3*)/*shaggy* (*sgg*) result in the specification of supernumerary tubule cells (Ainsworth *et al*., unpublished data). The *wg* gene is expressed in the innermost region of the proctodeum, where tubule cells arise during early stage 9 (Baker, 1988), suggesting that the Wg pathway activity could be a permissive signal for tubule cell allocation (Ainsworth *et al*., unpublished data).

2.8.3.3. Tubule Specification and Tubule Eversion

During stage 9 of embryogenesis, before any morphological differences are manifest, tubule cells can be distinguished from hindgut cells by changes in the expression pattern of Kr. At this stage, Kr expression refines from a broad domain throughout the hindgut to a narrow band of cells and then to four small clusters that will soon evert to form the tubule primordia. Previous reports have suggested that an early activity of Kr is to initiate the expression of the gene encoding the homeodomain-containing transcription factor Cut in the tubule primordium (Liu and Jack, 1992). Contrary to these data, however, it is found that, in the absence of Kr, Cut expression is initiated during stage 9, but is not subsequently maintained (Wan, 2001).

The combined activity of Kr and Cut are necessary for normal tubule eversion (Ainsworth *et al*., unpublished data). Tubule cells in embryos mutant for either *Kr* or *cut* fail to make the normal changes in cell shape, and either remain in the hindgut and proliferate in a manner typical of this tissue (in *Kr* mutants) (Gloor, 1950; Redemann *et al*., 1988; Harbecke and Janning, 1989) or form multilayered blisters that never develop into tubular structures (in *cut* mutants) (Liu and Jack, 1992). The transformation of tubule fate towards hindgut fate in *Kr* mutant embryos has led to the suggestion that *Kr* acts as a homeotic gene for tubule development (Liu and Jack, 1992). However, this transformation is incomplete as, later in development, the transformed cells secrete uric acid, a function characteristic of tubule cells (Skaer, 1993). For these reasons, other unknown factors besides *Kr* and *cut* must also be involved in directing tubule specific cell differentiation.

The tubules evert from the gut during stage 10 as four small buds, each containing approximately 20 cells. The newly formed tubule buds retain their apicobasal polarity as they evert. The genes regulated by Kr and Cut, which drive morphological rearrangement leading to tubule eversion, are not yet known but are likely to include molecules which regulate the cytoskeleton, modulate cell junctions and adhesion, and direct cell movement and cell shape changes.

The laterally positioned buds give rise to the anterior tubules, whereas the posterior tubules grow from the dorsally positioned buds (**Figure 1**). The exact details of how anterior versus posterior fate is specified are not known yet. The two pairs emerge at different positions relative to the dorsal–ventral axis and, therefore, one possibility is that anterior/posterior tubule fate may be controlled by the same factors that also pattern this axis (see **Chapter 1.2**). A second possibility is that the epidermal growth factor (EGF) pathway may be involved, because embryos with mutations in this pathway develop two, rather than four, tubules. In line with this, an EGF receptor ligand, Spitz (Spi), is secreted from the embryonic midline (Golembo *et al*., 1996). It is possible that this source of Spitz generates a morphogen gradient, to which the tubule primordial cells are exposed and specified in a concentration dependent manner.

2.8.4. The Tip Cell

2.8.4.1. The Tip Cell Lineage

Soon after the tubules bud from the gut at stage 10 of embryonic development, approximately 5 h AEL, a new cell lineage is born in each of the four tubule primordia, the tip cell lineage. This lineage arises

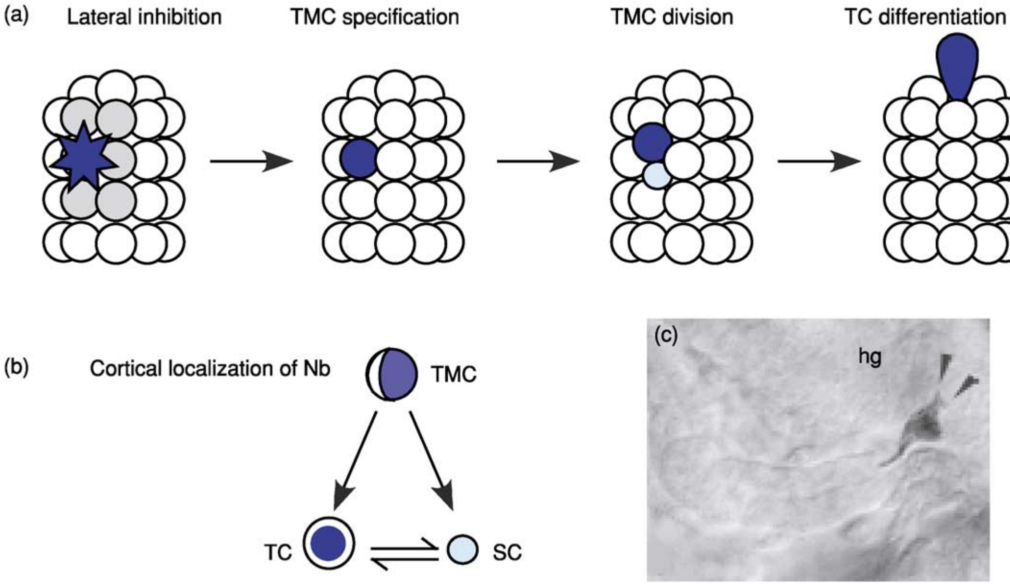

Figure 6 Specification of the tip cell lineage. (a) The tip mother cell (TMC) (dark blue) is selected from a group of proneural gene-expressing cells (gray) by a process of lateral inhibition. The TMC divides once to produce the tip cell (TC) (dark blue) and the sibling cell (SC) (pale blue). The TC differentiates, undergoing a characteristic change in morphology. (b) TC vs. SC fate is determined by asymmetric division of the TMC. The Numb (Nb) protein (white) is asymmetrically localized to one side of the TMC, and is inherited by a single daughter cell. Numb biases the competitive interaction that occurs between the two daughter cells, so that the cell that receives Nb becomes the TC. (c) A posterior MpT from a stage 15/16 *Drosophila* embryo stained with the TC-specific antibody 22C10, showing the long apical extension of the TC projecting into the tubule lumen, and the basal processes (arrowheads) that contact the nerve running along the hindgut (hg).

from the specification of the tip mother cell (TMC), a large cell morphologically distinguishable on the basis of its size relative to the other cells in the tubule (Hoch *et al*., 1994; Wan *et al*., 2000) (**Figure 6**). The TMC divides once, approximately 6.5 to 7.5 h AEL, during cell division cycle 16 (see Section 2.8.5.1), to produce two daughter cells, the tip cell (TC) and the sibling cell (SC) (**Figure 6**). The TC retains its distal position protruding from the tip of the tubule and forming a long apical extension into the tubule lumen. At this stage the TC exits the cell cycle and no longer divides. The TC and SC play at least two important roles in subsequent events during tubule development: (1) they are required for the regulation of cell division (see below and Section 2.8.5), and (2) they are required for tubule positioning as the tubules elongate (see Section 2.8.6).

The TC is required for cell proliferation in the tubule. If the TC is removed, either surgically (Skaer, 1989) or genetically (Hoch *et al*., 1994), a subset of the normal pattern of cell proliferation does not occur. TC-mediated control of cell division is described in detail below (see Section 2.8.5). TCs are not confined only to *Drosophila* embryonic tubules; they are also found in the developing Malpighian tubules of *R. prolixus*, in the locust *S. gregaria*, and in the cockroach *Periplaneta americana* (Skaer, 1989). The TCs of these other species share much in character with those of *Drosophila*: they are large, nonproliferative cells located at the distal end of each tubule. Cell ablation experiments have confirmed that the TC of *Rhodnius* is also required for normal cell division (Skaer, 1992), suggesting that TC-mediated control is a general mechanism for patterning cell division in insect tubules.

2.8.4.2. Specification of the TC Lineage

Specification of the TC lineage occurs by a mechanism reminiscent of the specification of neuroblasts in the neurogenic ectoderm (Hartenstein and Campos-Ortega, 1986; Hoch *et al*., 1994) (see **Chapter 1.10**). Before the tubules have everted, during late stage 9/early stage 10 (approximately 4.5 h AEL), expression of the proneural genes *achaete* (*ac*), *scute* (*sc*), and *lethal of scute* (*l'sc*) becomes apparent in four groups of 6–8 cells in the proctodeum (Hoch *et al*., 1994; Wan *et al*., 2000) (**Figure 6**). A little later, at the end of stage 10 (5–5.5 h AEL), proneural gene expression resolves to a single cell within each cluster, the TMC. In embryos lacking proneural gene function, the TMC is never specified, indicating that these genes, and those that they regulate, are important for TMC specification (Hoch *et al*., 1994). The TMC is singled out from

the proneural cluster by a process of lateral inhibition mediated by neurogenic components such as the ligand Delta (Dl), the receptor Notch (N), and elements of their signal transduction machinery (Brand and Campos-Ortega, 1988; Skeath and Carroll, 1992). The neurogenic gene products mediate competitive interactions between the cells in the cluster, such that one cell continues to express the proneural genes and subsequently adopts the TMC fate, while the remaining cells downregulate proneural gene transcription and adopt an alternative fate (see Section 2.8.5.3) (**Figure 6**). In the absence of neurogenic gene function, lateral inhibition fails and all cells in the cluster retain proneural gene expression and develop into TMCs.

The molecular details of the initial patterning of the proneural cluster within the tubule primordia are not known, but the process is likely to be under the control of the genes that pattern the posterior gut in the early embryo. An example of such a regulator is Wg, which is required to maintain *ac* gene expression in the cluster, and subsequently in the TMC. In embryos mutant for *wg*, *ac* expression begins to fade at 5–5.5 h AEL and is completely absent by stage 11 (6.5 h AEL) (Wan *et al.*, 2000). The requirement for a Wg signal at this stage is likely to be permissive rather than instructive, because ectopic expression of *wg*, although sufficient to maintain *ac* expression for a limited period, is not sufficient to establish supernumerary TMCs (Wan *et al.*, 2000).

The TMC undergoes one asymmetric cell division to produce two daughters; the tip cell (TC) and its sibling (SC) (**Figure 6b**). The TC versus SC cell fate distinction is again established by neurogenic gene-mediated lateral inhibition but, in this instance, the outcome is biased by the Notch inhibitor Numb (Nb) (Uemura *et al.*, 1989; Rhyu *et al.*, 1994; Berdnik *et al.*, 2002). Localization of the Nb protein in the TMC is initially symmetric but, as the cell enters mitosis, Nb localizes to a crescent on one side of the cell (**Figure 6b**). When the TMC divides, Nb segregates to a single daughter cell. The presence of Nb in one of the daughters renders that cell deaf to inhibitory signaling through Notch; it continues to express the proneural genes and subsequently adopts the TC fate. Without Nb, the SC transduces the Notch inhibitory signal, downregulates proneural gene expression, and so adopts the alternative, SC, fate. In *nb* mutant embryos, both daughters of the TMC transduce the Notch signal and two SCs form at the expense of the TC (Wan *et al.*, 2000). Conversely, ectopic expression of *nb* in both daughter cells suppresses Notch signaling and results in tubules with two TCs and no SCs (Wan *et al.*, 2000).

Similarities between the mechanisms that establish the TMC lineage and the neuroblast lineage have already been drawn. Further similarities between the TC and those of neural lineages are evident later in TC development. Towards the end of embryogenesis, the TCs begin to express a number of molecules that are typically expressed in neural cells such as *futsch* (the epitope recognized by the 22C10 antibody) (**Figure 6c**), *synaptotagmin* (*syt*), *synaptophysin* and the *Cysteine-string protein* (*Csp*) (Hoch *et al.*, 1994). In addition, during stage 16 the posterior TCs become closely associated with paired nerves that run on either side of the hindgut (Hoch *et al.*, 1994). Expression of these neuronal markers and the close association of the posterior TCs with hindgut nerves suggest the TC may have some neuronal function in tubule physiology. However, this possibility has not been examined further.

2.8.5. Proliferation of Malpighian Tubule Cells

2.8.5.1. Tubule Cell Number and the Pattern of Cell Division

There are two main cell types in the Malpighian tubules of *Drosophila*: the PCs and the StCs. The PCs arise from the division of cells derived from ectodermal cells in the proctodeum, whereas the StCs are recruited from a different tissue primordium and become incorporated into the postmitotic tubules. Control of cell division in primordial PCs is dealt with in this section, while StC recruitment is described in more detail below (see Section 2.8.7).

The number of PCs in mature Malpighian tubules is relatively constant between individuals: 484 cells, with 103 ± 8 in each posterior tubule and 144 ± 10 in each anterior tubule (Janning *et al.*, 1986). These cells are generated by division of primordial cells allocated in the proctodeum during stage 9 (see Section 2.8.3). The mature number of PCs is reached once proliferation is complete, midway through embryogenesis, at approximately stage 13.

Early divisions of the zygotic nuclei in *Drosophila* are synchronous and are not accompanied by cytokinesis until the 14th mitotic cycle. At this stage, cellularization occurs and cell division becomes spatially regulated (Foe, 1989). The first division of this type in the posterior gut (cycle 14) occurs in a domain that encompasses the hindgut and the tubule cells before they are specified (3.5 h AEL) (Foe, 1989). Once the tubule buds form, the pattern of cell division becomes distinct from that of the hindgut epithelium. In the first tubule-specific division (cycle 15), which occurs at 5.5–6 h AEL,

all cells in the tubule primordia divide synchronously. The second wave of mitosis (cycle 16, 7 h AEL) involves only a subset of tubule cells, those cells on the posterior side of the tubule, which again divide synchronously. Subsequent cycles (cycle 17 onwards) are nonsynchronous and are restricted to the distal region of the four tubules.

2.8.5.2. Regulation of Cell Proliferation

The invariant pattern of cell division described above is tightly regulated through the expression of two genes, *string* (*stg*) and *cyclin E* (*cycE*), that are limiting components of the cell cycle. The *stg* gene encodes the *Drosophila* homolog of the Cdc25 phosphatase and is involved in the regulation of the G_2/M transition of the cell cycle, whereas CycE regulates the G_1/S transition. The early synchronous divisions, up to and including cycle 13, are sustained by maternal contribution of these two gene products. However, the first cycle after cellularization (mitosis 14) and all subsequent divisions require the zygotic expression of *stg* to propel the cells though the G_2/M transition (Edgar and O'Farrell, 1990; Edgar *et al*., 1994). By cycle 17, maternal supplies of CycE are exhausted and, thus, division becomes additionally dependent on regulation of zygotic *cycE* expression to progress through the G_1/S transition of the cell cycle (Richardson *et al*., 1993; Knoblich *et al*., 1994). Cell division in the tubules is regulated by two pathways: by the Wg signaling pathway and by the *Drosophila* epidermal growth factor receptor (EGFR) pathway (Skaer and Martinez-Arias, 1992; Kerber *et al*., 1998; review: Duronio, 1999).

The *wg* gene is expressed in the proctodeum of stage 9/10 embryos and, at the time the tubule buds evert, all tubule cells express the gene. Once the tubules have completed their eversion, *wg* expression becomes restricted to cells on the posterior side of each tubule, and this pattern persists until late stage 12 (approximately 9 h AEL), with *wg* expression extending along the whole posterior length of the tubule (Skaer and Martinez-Arias, 1992). This pattern of *wg* expression covers the domain in which tubule cells divide during cycles 15 and 16. In *wg* mutant embryos the tubule cells arrest after M15 without going through the S phase of cycle 16 (Ainsworth *et al*., unpublished data). The molecular basis of Wg regulation of cycle 16 is not yet known. However, the role of the Wg pathway as a cell cycle regulator is separable from its role in the stabilization of TC fate. Thus, the Wg pathway has a dual requirement in the regulation of cell division in the tubules; in the posterior domain it permits cycle 16 progression, and secondly, stabilizes the TC, itself a source of the mitogenic signal, for cycle 17 and all subsequent divisions. In addition to these roles in regulating the mitogenic signal, the Wg pathway is required to pattern the cells that can respond to the signal. This role of the pathway is described in more detail below (see Section 2.8.5.3).

A mitogenic role for the EGF pathway in the tubules was indicated in early work showing that embryos mutant for either the EGFR or the gene encoding the ligand of the pathway, *spitz* (*spi*), possess very small tubules with a severe reduction in cell number relative to wild-type (Baumann and Skaer, 1993). More recent work has shown that EGFR pathway activity is required specifically for the late cell divisions in the tubules (Kerber *et al*., 1998). In embryos mutant for EGF pathway components, such as the EGFR or *seven-up* (*svp*), the early divisions (cycles 14–16) occur normally, but cell division arrests during cycle 17 (Kerber *et al*., 1998; Sudarsan *et al*., 2002). Previous work showed that late divisions, which are restricted to the distal region of the tubule, occur only in the presence of the TC and SC (Skaer, 1989; Hoch *et al*., 1994), thus suggesting that the TC/SC are the source of the EGF signal (**Figure 7**). This hypothesis was confirmed by the discovery that Rhomboid (Rho) and Star (S), two proteins required for the processing of Spi into its active secreted form (Lee *et al*., 2001; Urban *et al*., 2001), were expressed in both the TC and SC (Kerber *et al*., 1998; Sudarsan *et al*., 2002) (**Figure 7b**). Furthermore, the expression of *stg* and *cycE*, both of which are normally expressed in the distal region of the tubule during late divisions, is abolished in embryos mutant for either the EGFR, or for an effector gene of the pathway, *svp*. These data suggest a model whereby the EGF ligand Spi is the mitogenic signal for late tubule divisions. This signal, secreted from the TC/SC, stimulates the EGFR pathway in neighboring cells, activating Svp, which, in turn, induces the expression of *stg* and *cycE* and passage through the cell cycle (**Figure 7**).

Interestingly, the mature tubules of EGF pathway mutants have far fewer cells (between 23 and 27 cells) than would be predicted simply on the basis of cell cycle arrest at cycle 17 (wild-type tubules at the start of cycle 17 have approximately 70 cells). This discrepancy is due to the fact that the EGF pathway is additionally required to promote tubule cell survival (Sudarsan *et al*., 2002). In EGFR mutant embryos, tubule cell numbers begin to decline after cycle 16 and continue to do so until the end of embryogenesis, suggesting that cells die. If cell death is prevented in these embryos, the mature number

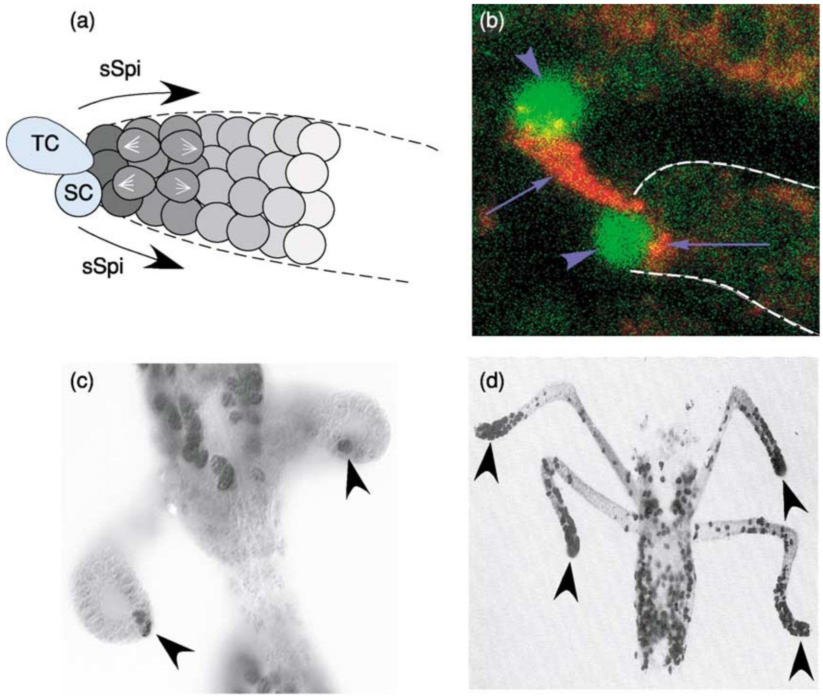

Figure 7 The tip cell (TC) and sibling cell (SC) are the sources of the mitogenic signal for late tubule cell division. (a) Schematic figure to show the TC and SC secretion of the epidermal growth factor (EGF) ligand Spitz (sSpi). A gradient of EGF pathway activity is generated in the tubule (dark gray, high activity; light gray, low fading to no activity), as sSpi diffuses from the TC and SC. Cell division occurs in response to EGF activity. (b) A confocal image showing expression of the serine-type peptidase, Rhomboid (red, arrows), specifically in the TC and SC (nuclear marker in green, arrowheads). Spi is only secreted after cleavage by Rho, and thus the TC and SC form the sole source of sSpi in the tubule. (c) Dissected tubules of a *Drosophila* embryo stained for the incorporation of BrdU to mark S phase of cycle 17; only cells in the distal region of the tubule, close to the mitogenic source, enter this cycle (arrowheads). (d) Dissected tubules from a *Rhodnius* embryo 55% through development stained for the incorporation of BrdU. Cells in S phase are predominantly in the distal region of the tubules (arrowheads) close to the TC.

of tubule cells is 74 ± 1, which corresponds exactly to the number of cells predicted on the basis of the mitogenic phenotype (Sudarsan *et al*., 2002).

2.8.5.3. Restriction of the Mitogenic Response

As the EGF ligand Spi is secreted from the TC and SC, only distal cells that are close to the source of Spi will receive the mitogenic signal and subsequently divide. Overlying this is a second level of regulation conferred by a restricted domain of competence to respond to the signal. Not all cells are capable of dividing, because they are not primed to respond. The molecular basis of this competency is the expression of two EGF pathway effector genes, *seven-up* (*svp*) and *pointed-P2* (*pnt*). Only those cells that express these two factors can transduce the EGF signal to induce the expression of *stg* and *cycE* and, thus, respond by dividing. How is this competence domain established?

Although transcription of *svp* and *pnt* is regulated in later stages by the EGF pathway itself, their initial transcription is independent of the pathway and is under control of the proneural genes and the *wg* pathway respectively. The TMC is specified during stage 10, and arises by the selection of a single cell from a group of proneural gene-expressing cells by the process of lateral inhibition (see Section 2.8.4) (**Figure 6**). A consequence of this process is that proneural gene transcription is maintained and upregulated in the TMC, while it is extinguished in the remaining cells of the cluster. Therefore, two cell populations are established with regard to proneural gene activity: a TMC, in which proneural activity is high, and a second population with lower, transient levels of activity. These levels are important, because regulation of proneural target genes occurs in a concentration dependent manner. High levels of activity in the TMC establishes the TC/SC fate and induces the expression of *rho*. In contrast, the low, transient level of activity in the other cells of the cluster is sufficient to activate the transcription of *svp* but not *rho* (**Figure 8**). Thus lateral inhibition segregates two cell fates within the proneural cluster: the primary TMC fate; and a second cell fate, for those cells competent to respond to the mitogenic signal by virtue of their expression of *svp* (Sudarsan *et al*., 2002).

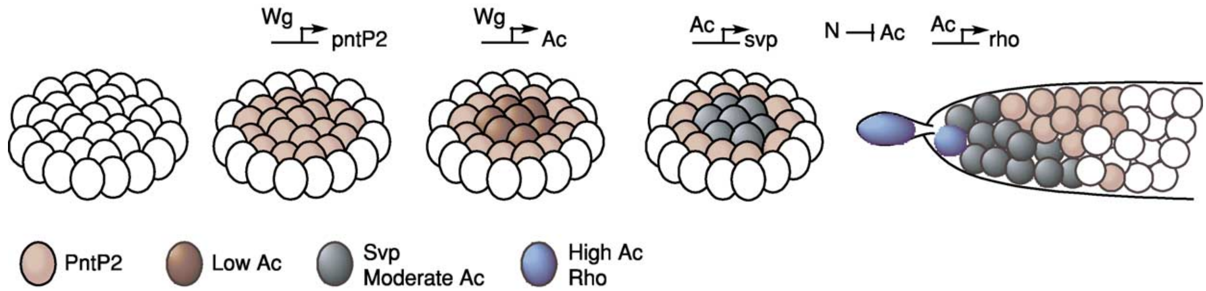

Figure 8 Model for the establishment of mitotic competence in *Drosophila* Malpighian tubules. Wg signaling activates the expression of *pntP2* in a subset of tubule cells (brown), and is required to establish proneural gene expression in the proneural cluster (represented by *ac*, dark brown). Moderate levels of Ac induce *svp* expression in the cluster (gray) but, as Ac expression increases in the TMC, a threshold for the initiation of *rho* expression is reached (blue). The TMC divides to produce the TC and SC (blue). As *ac* expression is lost from the SC by stage 12, the maintenance of *rho* expression from this time onwards is independent of Ac. The cells that originally formed the proneural cluster are competent to respond to EGF signaling by virtue of their expression of *pntP2* and *svp*. They divide in response to Spi secreted by the TC and SC.

These data also resolve a paradox relating to the phenotype of the neurogenic genes. Tubules of embryos mutant for any of the neurogenic loci have supernumerary TCs, because lateral inhibition fails, and all cells in the proneural cluster adopt a TC fate. Because the TC is the source of mitogenic signal, it might be expected that supernumerary TCs would induce more cells to divide, thereby producing tubules with many more cells than in the wild-type. However, in spite of excess signal, the tubules of neurogenic mutants have only 70 cells, the number found in tubules lacking TC/SCs. The discovery that lateral inhibition normally segregates two cell fates resolves this paradox. In neurogenic mutant embryos, all cells of the proneural cluster adopt the TC fate at the expense of the mitogenically competent cells. Therefore, despite the availability of elevated signal, no division occurs, because cells competent to do so have not been specified.

The second effector of the EGF pathway required to establish mitotic competence is *pnt*. The *pnt* gene is expressed on the posterior side of the tubules from stage 10 in a slightly wider domain than that of the proneural cluster, and is under control of the Wg pathway (**Figure 8**). It is not yet known whether this pathway directly upregulates the expression of *pnt*, but *pnt* expression is lost in *wg* mutant embryos and expands into the anterior domain of the tubule, when *wg* is expressed ectopically throughout the embryo (Sudarsan *et al*., 2002).

Thus, patterning of the later tubule cell divisions (which happens during stages 12–13) is established earlier in development, during stage 10. At this stage the progenitor of the mitogenic signal source, the TC and SC, is specified. In addition, a population of cells expressing both *svp* and *pnt* is established, and it is these cells that will respond to the mitogenic signal and subsequently divide. It is worth considering the reason why a competency domain needs to be established. Most tissues in the embryo go through three postblastodermal divisions and then cease to divide further. Therefore, the late tubule cell divisions are unusual and occur in a mitotically quiescent environment. It might be important to define the limits of division in such conditions so that, should mitogenic signaling become deregulated, the extent of the competence domain imposes an effective brake on tubule hyperplasia.

2.8.5.4. Endoreplication in the Postmitotic Tubules

Growth of the animal through larval life needs to be matched by increasing the excretory capacity of the tubules. In *Drosophila*, this is achieved not by increasing the number of tubule cells – cell division in the Malpighian tubules is complete by stage 13 of embryogenesis – but by cell growth. To permit this increase in cell size, every tubule cell undergoes several rounds of endoreplication (Smith and Orr-Weaver, 1991; Orr-Weaver, 1994). The tubules undergo seven endocytic cycles. The first endocytic cycle begins midway through stage 13, with all cells entering this cycle, and continues through larval and pupal development so that in the adult the DNA copy number is 252 (Lamb, 1982).

Endoreplication followed by cell growth also occurs in *Rhodnius* as a mechanism for increasing excretory capacity. Here, the first endocytic cycle occurs approximately 60% through embryonic development, as a wave involving every nucleus, starting with the proximal tubule cells and sweeping distally (Skaer, 1992). Unlike *Drosophila*, this first endocytic cycle is accompanied by a wave of nuclear but not cytoplasmic division, so that, by 75–80%

of development, all cells in the *Rhodnius* tubule are binucleate (Skaer, 1992). In *Rhodnius*, an endoreplicative cycle occurs at every larval molt, and this, in turn, is associated with an increase in cell size (Maddrell *et al*., 1985).

2.8.6. Morphogenesis, Cell Rearrangement, and Tubule Navigation

2.8.6.1. Tubule Morphogenesis

At stage 10, the tubules evert from the proctodeum forming four small buds, each containing approximately 20 cells. *Kr* and *cut* are expressed in the everting tubules during this time and, in the absence of either gene product, eversion does not occur normally, with tubule cells remaining in the hindgut or forming multilayered blisters on the hindgut (Gloor, 1950; Redemann *et al*., 1988; Harbecke and Janning, 1989; Liu and Jack, 1992). These phenotypes suggest that *Kr* and *cut* are likely to have a significant role in regulating factors that, in turn regulate morphogenetic events leading to eversion. A candidate for such a factor is *walrus* (*wal*), as mutations in this gene result in failure of eversion, with the tubule cells remaining as a ring in the proctodeum (Liu *et al*., 1999). The molecular nature of the *walrus* product, however, an electron transfer flavoprotein, does not immediately suggest what function it might play.

After eversion, until approximately stage 13, the main activity happening in the tubules is cell division. Relatively little cell rearrangement occurs during this phase, possibly because the mechanism by which cells rearrange and the associated modifications in cell adhesion are not compatible with cell division. Starting midway through stage 13 and continuing until stage 16, the tubules undergo a dramatic, but very stereotypical change in morphology (**Figure 1**). At stage 13 the tubules are relatively short, with approximately six to ten cells surrounding the tubule lumen (Skaer, 1993). Tubule elongation results from a series of convergent-extension movements so that, by stage 16 the length of each tubule has dramatically increased, while the diameter decreases, so that only two cells surround the lumen. In a similar manner, cell rearrangement in the tubules of *Rhodnius* begins only after cell division has ceased. As the tubules undergo convergent-extension, their length increases approximately sixfold and their diameter narrows, with the number of cells around the circumference of the lumen decreasing from 8 to 12 immediately before elongation, to just two cells afterwards (Skaer, 1992).

The process of convergent-extension is driven by organized cell rearrangement and is likely to be regulated by two classes of molecules: those providing spatial information to orchestrate the movement, and those that execute the cellular processes required for rearrangement. It would be sufficient to define a single axis to provide the spatial information required for cells to determine their position within the plane of this single cell-layered epithelium. The cells could then shift position relative to one another so that the net movement in the tissue occurs in a coherent manner. The molecular basis by which this is achieved is not known. Preliminary data, however, suggest that components of the signaling pathway that establishes planar polarity in other tissues are also required for normal convergent-extension movements in the tubules (Wan *et al*., 2001).

Mutagenesis screens for genes affecting tubule morphogenesis have identified genes required for the execution of cell rearrangement (Harbecke and Lengyel, 1995; Jack and Myette, 1999; Liu *et al*., 1999). Unsurprisingly, a number of these genes have direct roles in regulating cell shape, cell movement, and various aspects of cytoskeletal reorganization. The *zipper* (*zip*) gene which encodes the nonmuscle myosin heavy chain, is required and is necessary for the cell shape changes and movements associated with morphogenesis to occur (Young *et al*., 1993; Blake *et al*., 1999). The *ribbon* (*rib*) gene, which encodes a nuclear protein with a BTB/POZ domain, is also required for cell shape changes during tubule morphogenesis and may act by regulating the actin cytoskeleton (Jack and Myette, 1997; Blake *et al*., 1999; Shim *et al*., 2001). The *yolky/crooked neck* (*yok/crn*), *mummy* (*mmy*), *foreclosed* (*fcl*), *lines* (*lin*), and *buttonhead* (*btd*) genes all appear to be required for the elongation process, as the tubules in embryos mutant for these loci do not extend, but are instead distended and variable in diameter (Harbecke and Lengyel, 1995). However, the exact roles of these genes during elongation have not been elucidated.

In addition, members of the small Rho guanosine triphosphatase (GTPase) subfamily are required for normal elongation. Expression of either dominant negative or constitutively active versions of Rho, Rac, or Cdc42 result in defects in tubule elongation (Skaer *et al*., unpublished data). These small GTPases have been shown to have multiple roles in coordinating cell behavior during morphogenesis, including modification of the cytoskeleton and the adhesive properties of cells, junctional adhesion, and effects on gene transcription (Hall, 1998; Etienne-Manneville and Hall, 2002). Any one or a combination of these factors may cause the tubule defects observed when GTPase function is perturbed.

2.8.6.2. Organizing Tubule Arrangement within the Embryo

Throughout the elongation process, the tubules course a remarkably stereotypic path through the embryo and, by the time elongation is complete at stage 16, each tubule has taken up an invariant three-dimensional position within the body cavity (**Figure 1**). In addition, the TC of each tubule locates to an exact position within the embryo. One of the anterior TCs contacts the allary muscle of the dorsal vessel in abdominal segment A3 (Skaer *et al*., unpublished data), while the other one makes contact with the visceral mesoderm at the base of the ureter (Skaer, 1993). The two posterior TCs contact the paired nerves that run along either side of the hindgut (Hoch *et al*., 1994). The stereotypic path that the tubules take during elongation and the final destination of the distal tips critically require both the TC and the SC. In *numb* (*nb*) mutant embryos, in which two SCs but no TCs are formed, the precise configuration is lost, and the distal ends randomly locate within the embryo (Wan *et al*., 2000). A similar outcome occurs when SCs fail to be specified, a condition which can be induced experimentally by ectopic expression of *nb* in the TMC (Wan *et al*., 2000). These results indicate that both the TC and the SC have distinctive roles in ensuring the correct localization of the tubules within the embryo. It is not known if the TCs and SCs are required only to anchor the tubule tips at specific positions within the embryo or whether they have a pathfinding role in tubule navigation.

The distal tip cell (DTC) of the *Caenorhabditis elegans* gonad arm shares much in common with the TC in insect tubules. It too is a large cell located at the distal tip of a tubular epithelium, which regulates proliferation in the gonad by producing a mitogenic signal (Kimble and White, 1981; Austin *et al*., 1989; Henderson *et al*., 1994). In addition to this mitogenic role, the DTC also controls morphogenesis of the gonad arm, providing a paradigm for morphogenetic control executed at the level of a single cell. The DTC leads the outgrowth of each arm to produce the bilaterally hooked structure that characterizes the mature organ. *Cell death abnormal-5* (*ced-5*), a member of a gene family that also includes human DOCK-180 and *Drosophila myoblast city* (*mbc*) (Wu and Horwitz, 1998; Erickson *et al*., 1997), is expressed in the DTC and is required for the morphogenetic movements in the gonad. These genes encode regulators of the Rac GTPase (Klyokawa *et al*., 1998; Nolan *et al*., 1998) which has been shown to have multiple roles in controlling cell morphogenesis, for example, controlling cell protrusions required for cell movement (Hall, 1998; Ridley *et al*., 1992; Etienne-Manneville and Hall, 2002). It is possible that the TC and/or SC in *Drosophila* plays an analogous function to the DTC in controlling tubule navigation. This parallel may extend to the molecular mechanism by which morphogenesis is executed, because tubule navigation also goes awry in embryos mutant for *mbc* (Ainsworth *et al*., 2000).

A number of other factors have been implicated in morphogenetic movements in the *C. elegans* gonad including GON-1 (Blelloch and Kimble, 1999). GON-1 is a ADAMTS metalloproteinase, a proteolytic enzyme that degrades extracellular matrix components and so prepares the way for cell migration and tissue remodeling during organogenesis. The *Drosophila* genome contains a number of metalloproteinases but their function during morphogenesis has not been studied in detail. Indirect evidence for a role for metalloproteinases in tubule morphogenesis comes from studies into *papilin* (*ppn*), a large glycoprotein sharing a number of common domains with ADAMTS metalloproteinases (Kramerova *et al*., 2000). Papilin inhibits the activity of metalloproteinases *in vitro* and has been shown to cause defects in tubule morphogenesis, when ectopically expressed in the *Drosophila* embryo (Kramerova *et al*., 2000).

The data from the DTC in *C. elegans* and the TC/SC in *Drosophila* suggest that the activity of specific cells in guiding tissue morphogenesis may be a conserved feature of tubulogenesis. It will be interesting to examine the role of metalloproteinases and other molecules similarly expressed in these cells, to determine if the molecular basis of this control is also conserved. As the TC and SC have distinctive roles in tubule morphogenesis, it will also be interesting to discern the individual contribution of these two cell types.

2.8.6.3. Tubule Navigation: The Role of Other Tissues

As the tubules extend, they make contact with other tissues within the embryonic cavity, and these tissues are often necessary for proper tubule morphogenesis. It is likely that they act as substrates to provide traction for tubule movement. One example of this is the gut visceral mesoderm. In *heartless* (*htl*) mutants, in which the gut visceral muscle does not form (Beiman *et al*., 1996), the anterior tubules do not extend forward but become mislocalized within the body cavity (Skaer *et al*.,

unpublished data). In addition to this role, it is possible that these tissues have a more instructive role, by providing spatial cues to orient the tubules as they navigate.

2.8.7. Cell Recruitment to the Malpighian Tubules

2.8.7.1. Stellate Cells are Derived from a Separate Tissue Primordium

The mature tubules contain two main cell types, PCs and StCs, the latter being conspicuous in the adult by their very distinctive star-shaped morphology, from which they get their name (**Figure 9**). These two cell types perform different physiological functions in the tubules: PCs are the main channel for cation exchange, whereas StCs facilitate chloride ion and water movement (Dow *et al.*, 1995; O'Donnell *et al.*, 1996, 1998) (see Section 2.8.2.1) (**Figure 2**).

There is a total of 484 PCs (Janning *et al.*, 1986) and 110 StCs (Sozen *et al.*, 1997) in the four mature *Drosophila* tubules. The StCs are regularly interspersed along the length of the four tubules with the exception of the proximal domain, from which they are absent (**Figure 9**). Until recently, it was assumed that the StCs were derived from the same tissue primordium as the PCs, but recent work has shown that the origin of the two cell types is different. The 484 PCs are generated by division of the primordial cells derived from the ectoderm (see Section 2.8.5). In contrast, lineage tracing studies have shown that the StCs arise from the mesoderm and that they migrate to and subsequently integrate into the postmitotic tubules (Denholm *et al.*, 2003). The precise origin of the StCs is a region of posterior mesoderm that also gives rise to the caudal visceral mesoderm (CVM). The posterior mesoderm internalizes with the amnioproctodeal invagination during gastrulation and, by stage 9, lies over the hindgut. At this stage, a subset of the posterior mesoderm, the CVM, begins to migrate anteriorly. These cells subsequently provide the muscle founder cells for the longitiudinal visceral muscles of the midgut (Kusch and Reuter, 1999; Lorén *et al.*, 2001; Martin *et al.*, 2001) (**Figure 10a**). At stage 9, as the CVM begins to migrate anteriorly, the tubules evert from the hindgut and bisect this mesodermal population (**Figure 10a**). The subset of mesodermal cells on the posterior side of the tubules remain associated with the tubules and later become the StCs.

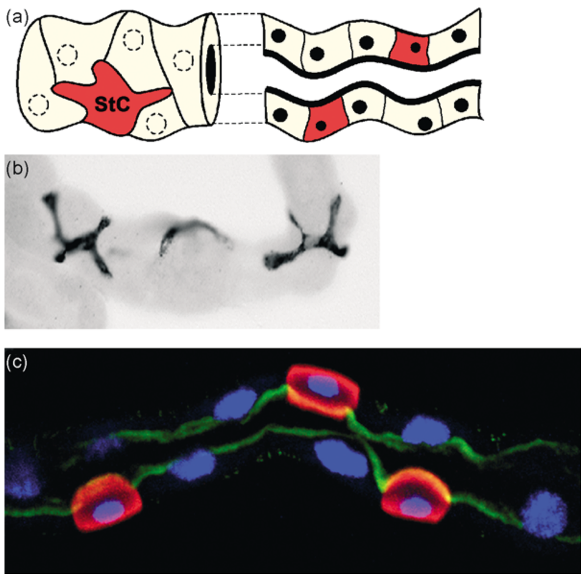

Figure 9 The cells of *Drosophila* Malpighian tubules. (a) Schematic representation of an adult Malpighian tubule. Two cell types are depicted: the principal cells (PCs) (yellow) and the stellate cells (StCs) (red). The PCs are interspersed with the StCs throughout the distal region of the tubule. (b) In the adult fly, the StCs have a star-shaped morphology from which they derive their name. In this experiment, the StCs are distinguished from PCs by a genetic label (they have succinic hydrogenase positive nuclei) used to trace lineage (see Denholm *et al.* (2003) for details). (c) The tubules from a third instar larva stained with an enhancer trap line (red) inserted in the *teashirt* (*tsh*) gene, which marks out StCs, for F-actin (green), and for DNA (blue). The StCs, but not PCs, express Tsh. Both cell types exhibit apicobasal polarity, as demonstrated by the accumulation of F-actin in the microvilli on the luminal side of the cell.

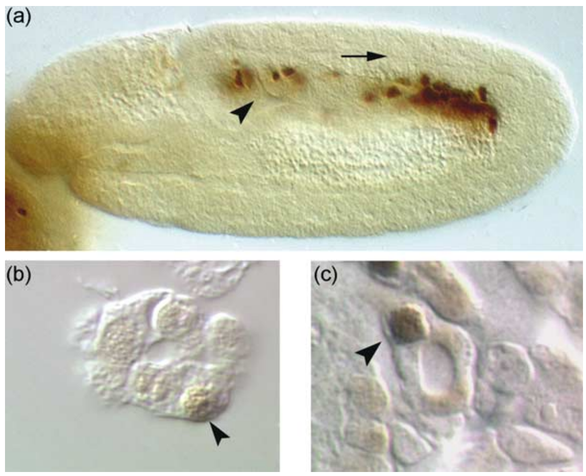

Figure 10 Stellate cells are derived from a mesodermal population and subsequently integrate into the tubule epithelium. (a) An extended germband embryo stained for an enhancer trap line that marks a subset of the posterior mesoderm. While the majority of this mesodermal population (the CVM) migrates anteriorly during stage 10–11 (arrow), a subset remains associated with the tubules as they evert from the hindgut (arrowhead). (b, c) Sections through a stage 13 embryonic tubule demonstrating a Tsh-positive StC (dark brown) in the process of integration (b) and a stage 15 embryonic tubule showing a Tsh-positive StC (dark brown) fully integrated into the tubule epithelium (c).

During the period between stages 9 and 12, the StCs adhere to the tubule epithelium and are mesenchymal in character. During stage 13, StCs start to express the transcription factor encoded by *teashirt* (*tsh*) and begin to integrate into the tubule epithelium (**Figure 10b** and **c**). Tsh is critical for this process, because StCs do not integrate in *tsh* mutant embryos (Skaer *et al*., unpublished data). During or subsequent to their integration, the StCs polarize and, by the end of embryogenesis, become epithelial in character with a defined apical membrane and a polarized cytoskeleton (Denholm *et al*., 2003). Notably, this mesenchymal to epithelial transition does not involve the activity of Crumbs (Crb), a protein required for establishing and maintaining epithelial integrity in ectodermally derived epithelia, as Crb is not expressed in the StCs.

The processes by which the StCs are specified, recruited, integrated, and subsequently polarized is still not completely understood. However, one factor that has been shown to play a role is Hibris (Hbs), a single transmembrane spanning immunoglobulin-like molecule. In *hbs* mutants, StC numbers are reduced to 68 ± 4 (cf. 110 in wild-type tubules), clearly demonstrating a role for *hbs* in StC development (Denholm *et al*., 2003). Hbs has been shown to interact with other immunoglobulin-like molecules such as Sticks and stones (Sns) and Dumbfounded (Duf) during myogenesis, where it is required for normal myoblast attraction and fusion (Artero *et al*., 2001; Dworak *et al*., 2001). Although the precise role of Hbs during StC development is not yet established, it is intriguing to speculate that similar heterotypic interactions may occur between Hbs in the StCs and other immunoglobulin-like molecules in the neighboring PCs, and that this interaction may be required in order for StC integration to be stabilized.

These data provide the first evidence that Malpighian tubules are derived from cells of a separate origin, and suggest that the development of these simple epithelial tubes may be more complex than previously thought. StCs are not just a peculiarity of *Drosophila*; they have been discovered in other Diptera including the fleshfly *Sarcophaga bullata*, in the mosquitoes *Anopheles* and *Aedes aegypti*, and in the cockroach *Periplaneta americana*. It will be interesting to determine the origin of the StCs in these species. However, it is also known that other insect species do not have StCs, an example being *Rhodnius*, which has secretory cells of a single type (see **Figure 2**). These findings raise two interesting questions: why is physiological function divided between two separate cell populations in some species but not in others; and secondly, how did a bipartite system consisting of cells from separate origins first evolve?

2.8.8. The Development of a Physiologically Competent Tissue

Unlike most other aspects of Malpighian tubule development, maturation of physiological function has not been analyzed in detail in *Drosophila*. The study of Malpighian tubule physiology has been conducted largely in bigger insect species, such as *Rhodnius*, that possess tubules more amenable to physiological studies. In addition, tubule development occurs over a longer period in these species and this makes it easier to correlate changes in cell architecture with the development of physiological competence brought about by these changes. For these reasons, the following section describes the cellular and structural changes associated with the maturation of physiological competence in *Rhodnius prolixus*.

2.8.8.1. The Onset of Physiological Activity in *Rhodnius prolixus*

The onset of physiological activity in *Rhodnius* Malpighian tubules has been analyzed in two ways: first, by measuring secretory rates and second, by examining their ability to transport specific classes of molecules (Skaer *et al*., 1990). Measurements of either urine production in freshly fed intact animals or secretion from isolated tubules demonstrate a linear increase in the rate of secretion from approximately 24 h after hatching until about 7–8 days post hatching, when the rate reaches a plateau (**Figure 11**). Embryonic tubules or tubules from animals younger than 24 h are not able to secrete fluid, suggesting that the onset of secretory capability occurs at approximately 1 day after hatching. Despite this, maximal secretory capacity is only achieved 7–8 days post hatching (**Figure 11**). It is notable in this regard, that *Rhodnius* do not usually feed immediately after eclosion but wait a number of days before taking their first blood meal.

Maturity of tubule function can also be assessed by analysis of ability to transport different classes of solutes. One such endogenous solute is uric acid, which is transported from the hemolymph by the cells of the lower tubule into the tubule lumen, where it precipitates (O'Donnell *et al*., 1983). Small amounts of uric acid begin to appear in the lumen at 3 days prior to hatching. During the subsequent 72 h, the amount of uric acid increases, so that, by the time of hatching, the whole lower third of the tubule is filled with uric acid crystals. In addition to uric acid, Malpighian tubules have been shown to transport a number of other compounds. One of

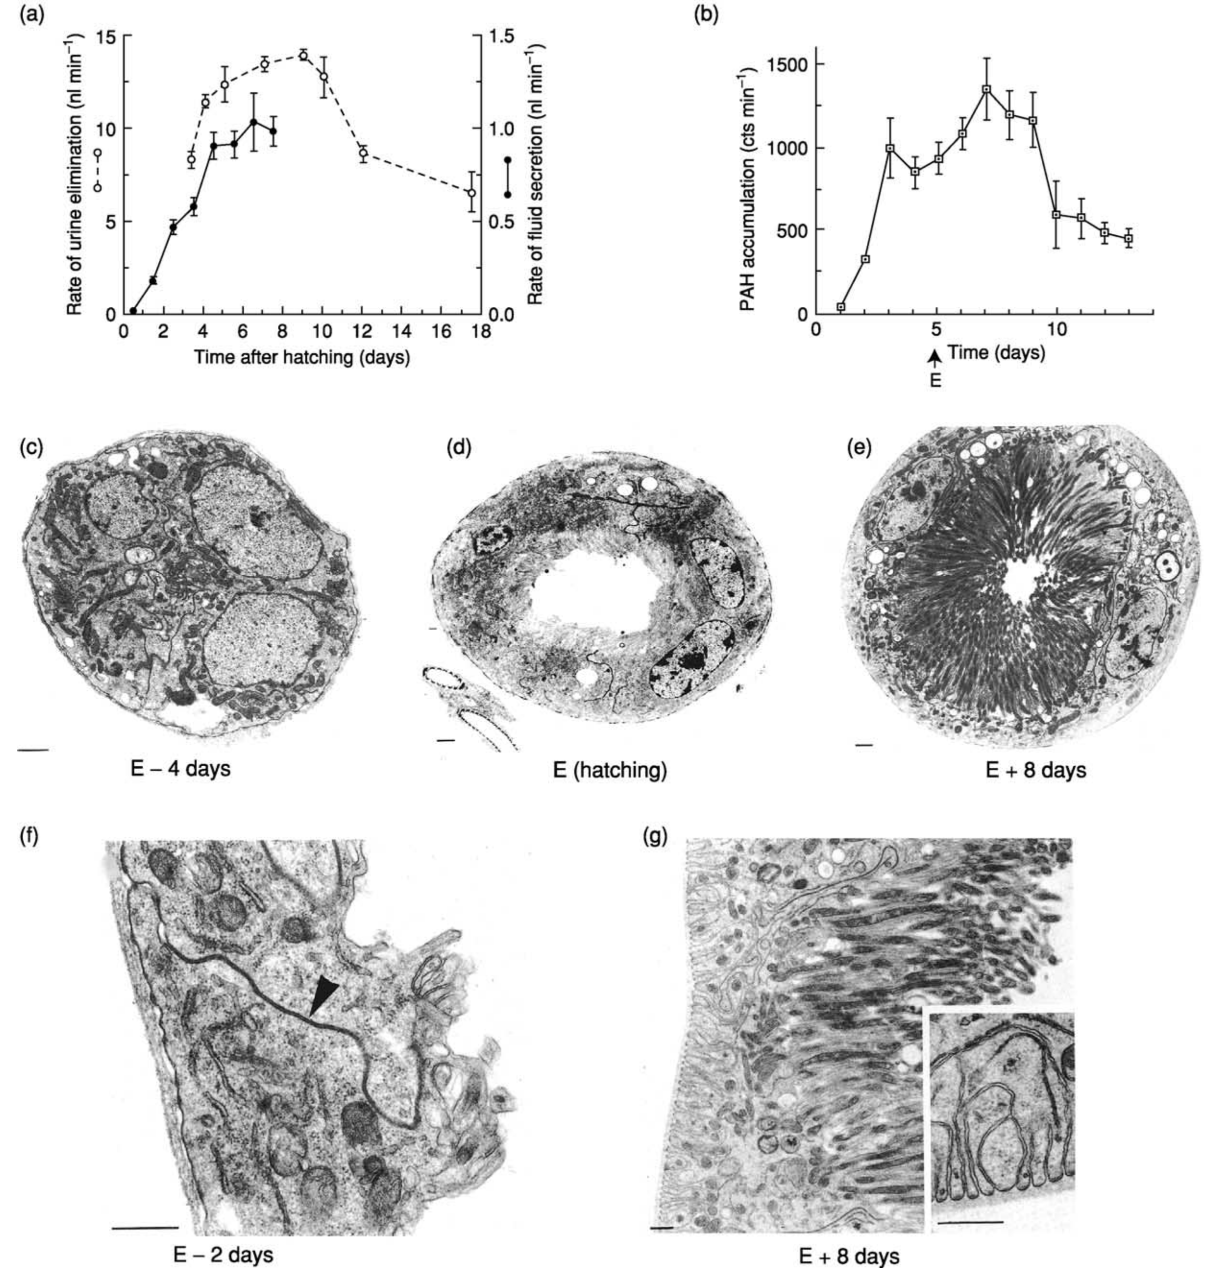

Figure 11 Physiological and structural maturation of the Malpighian tubule of *Rhodnius prolixus*. (a) Maximum rates of urine elimination by freshly fed first instar *Rhodnius* (broken line) and rates of fluid secretion by individual, isolated Malpighian tubules (solid line). Both parameters demonstrate a linear increase until approximately 7–8 days after hatching, when the rates plateau. (b) Accumulation of *p*-aminohippunic acid (PAH) in embryonic and hatchling *Rhodnius* tubules as measured after 30 min of exposure to radiolabeled PAH. Day of emergence is indicated (E). PAH transport begins at approximately 4 days before hatching and the rate of transport continues to rise until about 3 days postemergence. (c–e) Transverse sections of upper Malpighian tubule at different stages of development showing the dilation of the lumen and the elaboration of apical and basal membranes: (c) 4 days before hatching; (d) day of emergence; (e) 8 days postemergence. Scale bar = 1 μm. (f, g) Longitudinal section through an upper Malpighian tubule showing the elaboration of the basal and apical membranes through development: (f) 2 days before hatching; (g) 8 days postemergence. Inset in (g) shows the basal infoldings at higher magnification. Scale bar = 500 nm. Arrowhead in (f) indicates the intercellular junction.

these, *p*-aminohippuric acid (PAH), is transported by the cells in the upper region of the tubule (Maddrell *et al*., 1974). Transport of PAH begins at approximately 4 days prior to hatching and accumulates rapidly in the tubules throughout the remainder of embryonic development (Figure 11).

These data demonstrate that there are at least two periods of functional maturation, separable by

several days. The first period, which begins 3–4 days prior to hatching, corresponds to the ability to transport organic solutes such as uric acid and PAH. The second phase, which occurs over the period 1–8 days after hatching, is the onset of fluid transport. These different phases of functional maturation correlate with underlying changes in cell architecture. An important step for the first phase appears to be the establishment of mature septate junctions. During the earlier stages of embryogenesis, tubule cells are linked by *adherens* junctions and gap junctions, but it is not until approximately 4 days before hatching that mature septate junctions are assembled (Skaer *et al*., 1990). The likely function of septate junctions is to reduce the permeability of the paracellular pathway by increasing the effective path length and by the retention of extracellular material between adjacent cells, thereby reducing the possibility of bulk flow of fluid between the cells. Mature septate junctions have been shown to possess these properties (Skaer and Maddrell, 1987; Skaer *et al*., 1987). Concomitant with septate junction assembly, and representing an additional requirement for the first phase, is the formation of the lumen (**Figure 11**). At 4 days before hatching, there is no clear lumen in the tubules. However, 2 days later (2 days before hatching), a lumen of approximately 10 μm in diameter forms (Skaer *et al*., 1990). The lumen diameter continues to expand until at least day 8 after hatching. The formation of a lumen provides space for the deposition of the organic solutes that the tubules begin to transport at this stage. It is possible that dilation of the lumen is a passive process, as the high concentrations of solutes in the lumen are likely to draw in water by osmosis.

The second phase in the development of physiological function, the onset of fluid transport, begins soon after hatching and continues for 7–8 days. This phase is associated with a considerable reorganization of the apical and basal membrane architecture and the redistribution of cellular organelles (**Figure 11**). At 2 days before hatching, microvilli begin to appear on the apical surface. At first, they are small and sparsely distributed but, by the day of hatching, they have formed a dense border covering the entire apical surface (**Figures 3** and **11**). The microvilli continue to grow both in length and density so that, by day 8 after hatching, they almost fill the luminal space. Over a similar period, elaboration of the basal membrane occurs, first by forming simple fingerlike folds that later interdigitate to generate the convoluted basal membrane architecture of mature tubules (**Figure 11**). The density of mitochondria associated with the basal infoldings and apical microvilli also increases dramatically over this period. It is likely that specialization of the membrane, through localization of specific receptors, ion pumps, and channels, occurs during this period. These changes in cell architecture increase the surface area of the membrane in preparation for the prodigies of excretion called for by the immense size of the first feed. It has been calculated that an animal can excrete a volume of fluid equivalent to the unfed body weight in the space of 40 min (Maddrell, 1991).

2.8.8.2. Physiological Maturation in *Drosophila*

In *Drosophila*, the transport of solutes and urates, in particular, is established before the end of embryogenesis. The first evidence of physiological activity is the accumulation of uric acid in the posterior tubules beginning at stage 17 of embryogenesis (**Figure 1**). Unlike *Rhodnius*, however, *Drosophila* larvae begin to feed almost immediately after hatching, and it is necessary that the tubules are competent to transport fluid by this time.

For the reasons outlined above, the developmental changes associated with physiological maturation in *Drosophila* tubules have not been analyzed in as much detail as those of other insect species such as *Rhodnius*. However, classical morphological descriptions of the *Drosophila* tubule reveal that spatial differences in cell type and tissue architecture exist along its length (Wessing and Eichelberg, 1978) (see Section 2.8.2.3) (**Figure 5**). The tailoring of physiological assays for use in *Drosophila* (Dow *et al*., 1994) has allowed the integration of these classically defined morphological descriptions with physiological function (see Section 2.8.2.3).

2.8.8.3. Physiological Maturation in *Drosophila*: A New Perspective

To date we know relatively little about how the tubules of *Drosophila* progress to physiological maturation. The integration of classical morphological description with physiological analysis is now permitting a correlation between form and function. How these specializations occur and are regulated during development is still largely unknown. Understanding the development of physiological maturation remains one of the challenges for the future, and *Drosophila* provides a unique system in which to address this. It is one of only a few insect with a sequenced and comprehensively annotated genome. This data forms the basis from which candidate genetic approaches can be performed to uncover new molecules required for a given physiological process. Complementary to this approach is the ease with which mutations can be generated

in a chosen gene (if mutant stocks of the gene do not already exist) and their phenotype analyzed at a morphological and/or physiological level. In addition, transgenic technology delivers a whole suite of useful techniques. An enhancer trap screen has already revealed novel tubule domains with differential patterns of gene expression (Sozen *et al.*, 1997). Additional screens such as this are likely to reveal not only the factors underlying physiological function but also those required for physiological maturation. Transgenesis technologies also allow gene expression and function to be manipulated in a defined subset of cells in any given tissue of an otherwise normal animal, a luxury not normally afforded to physiologists. Furthermore, advances in immunocytochemistry and the ability to label molecules *in vivo* can reveal the cellular location of proteins or protein complexes, and can be used to visualize molecular interactions. These techniques should help us to understand the function that specific molecules play during tubule differentiation and physiological maturation.

2.8.9. Malpighian Tubule Development: Toward a Comparative Approach

Over the course of the last 50 years, we have learnt much about the cellular and molecular aspects of physiological function of the Malpighian tubules from a variety of insect species (review: Dow and Davies, 2001). Unsurprisingly, many aspects of tubule function are conserved across the insect class and, consequently, the early studies serve to inform and accelerate physiological analysis in other species. In this chapter, a description of tubule development in *Drosophila* is presented. Over the course of the past 15 years, a relatively comprehensive picture of many aspects of tubule development has been pieced together for this species. In contrast, our knowledge of tubule development in other species is, at best, rudimentary. A challenge for the future will be to determine the way in which tubule development occurs in other insect species. The knowledge we have gained from the analysis in *Drosophila* should provide a framework to facilitate this approach. The mechanism of TC-mediated control of cell proliferation in the tubules of *Rhodnius* (see Section 2.8.4.1) is an example where a comparative approach has proved fruitful. In addition, the genomic sequence of *Drosophila melanogaster*, *Drosophila pseudoobscura,* and of the mosquito *Anopheles gambiae* are now published and, with other insect genome sequence projects well under way (Kaufman *et al.*, 2002), a comparative approach will become easier.

Of particular interest will be those cases where the mode of tubule development is very different from *Drosophila*. A good example is the locust, in which additional tubules develop during each instar, with every tubule possessing a TC (Savage, 1956). This prompts a number of interesting developmental questions: is cell proliferation in the locust tubules also under the control of the TC? Does TC specification in the locust occur by the same molecular mechanism as in *Drosophila*, and if so, are all TCs specified during embryonic development and then remain quiescent until required, or are they specified *de novo* at each larval molt? Are new primary Malpighian tubule cells specified at each molt or do TCs activate a dormant stem cell population to generate new tubules? Does the locust tubule possess StCs and if so, is the mechanism of their recruitment similar to that in *Drosophila*? Furthermore, there are some insect species that lack tubules altogether, possessing instead the more ancestral excretory system of coelomoduct nephridia. Accordingly, the comparative analysis could be extended further to determine the relationship between these two organs. Questions of this nature will extend our understanding of insect excretory system development in particular, and illuminate evolutionary aspects of organogenesis in general.

2.9.1. Introduction

Since the first publication of this series nearly two decades ago, the fat body has emerged as a dynamic tissue involved in longevity, in coordinating insect growth with metamorphosis, and in mediating the innate immune response. Developmental studies on the insect fat body suggest intriguing cell lineage relationships between fat cells and other mesoderm derivatives and have provided insights into tissue remodeling. This chapter will discuss the genetic basis of embryonic fat-cell determination and differentiation, the origin of the adult fat body, the role of the fat body as an endocrine organ and, finally, will describe studies on tissue remodeling of the fat body during metamorphosis. Emphasis is on functional studies that address underlying mechanisms and includes descriptive studies as they relate to the understanding of these mechanisms. Because of advances in cell biology tools, the completion of the genome project, and the extensive genetics, most of our recent understanding of the fat body comes from studies in *Drosophila melanogaster* (Flybase, 2003). As such, much of this chapter deals with this organism but, where possible, studies from other insects are included. Several topics relating to the fat body are not represented in this chapter but have been discussed in recent reviews: storage proteins (Telfer and Kunkel, 1991; Wheeler and Martinez, 1995; Haunerland, 1996; Burmester and Scheller, 1999), regional expression in the fat body (Haunerland and Shirk, 1995; Harshman and James, 1998), and the innate immune response.

The insect fat body is often, but *inaccurately*, described as the insect equivalent of the mammalian liver. Foremost, the fat body and liver are derived from different germ layers; the fat body is mesodermally derived whereas the liver arises from the endoderm. Furthermore, even though the fat body shares some metabolic processes with the liver, it is not the sole tissue to carry out these functions. Alcohol dehydrogenase (Adh), a key enzyme in alcohol metabolism in the mammalian liver, is present in the fat body, but Adh is also present in the middle and anterior midgut (Fischer and Maniatis, 1986). The activity of Adh in the fat body is the critical observation that promoted the idea that the fat body is involved in detoxification and is the functional analog of the mammalian liver. However, detoxification in insects is primarily a function of the midgut where, similar to the liver, the smooth endoplasmic

reticulum is abundant and functions to modify or detoxify chemicals (Locke, 2003). In constrast, the insect fat body almost never has a smooth endoplasmic reticulum (Locke, 2003).

Molecular studies aimed at understanding the transcriptional control of *Adh* led to the notion that the tissue-specific control of *Adh* in the fat body is mediated by DNA-binding proteins also involved in liver-specific gene transcription (Sondergaard, 1993 and references therein). The *D. melanogaster B-box factor-2* (*BBF-2* also known as *Bbf1*) gene codes for a transcriptional activator of *Adh* (Abel *et al.*, 1992). BBF-2 is a member of the CREB/ATF family of transcription factors that are also active in the liver. Based upon Northern blot analysis, *BBF-2* is expressed throughout the life cycle of *D. melanogaster*, albeit at various levels (Abel *et al.*, 1992); the highest levels of *BBF-2* mRNA are seen during embryogenesis and in adult males. Northern blot analysis of early third-instar larvae also demonstrated that *BBF-2* mRNA is present in trachea, gut, and fat body. Hybridization studies to confirm the tissue-specific expression of *BBF-2* transcripts has not been reported, and *BBF-2* is not expressed in the embryonic fat body (D.K. Hoshizaki, unpublished data). Thus, *BBF-2* is not fat-cell specific nor is it co-expressed with *Adh* in the embryonic fat body.

A second *D. melanogaster* gene with homology to a liver transcriptional activator gene is *HNF-4(D)* (Zhong *et al.*, 1993). *HNF-4(D)* (also known as *Hnf4*) is a homolog of *HNF-4* (*Hepatic Nuclear Factor-4*), a steroid-hormone receptor gene encoding a mammalian transcription factor involved in the activation of a wide array of liver-specific genes (Costa *et al.*, 1989; Sladek *et al.*, 1990; Mietus-Snyder *et al.*, 1992). *HNF-4(D)* is reported to be expressed in the embryonic fat body, salivary glands, and the anterior and posterior midgut primordia. Further analysis of *HNF-4(D)*, however, demonstrated that *HNF-4(D)* is not expressed in the embryonic fat body, nor does the lack of *HNF-4(D)* affect the formation of the embryonic fat body or the expression of fat body genes (Hoshizaki *et al.*, 1994). Although the fat body and mammalian liver carry out some of the same functions, the assertion that the fat body is the insect equivalent of the mammalian liver should be made with care.

2.9.2. Origin of the Embryonic/Larval Fat Body

The embryonic fat body is derived from cells that are arranged in a metameric repeating pattern within the mesoderm. The formation of the progenitor fat cells is dependent upon the subdivision of the mesoderm and inductive events from the ectoderm. A descriptive account of the developing fat body from its various progenitor cells is presented here, and is followed by discussions of the cell patterning events that lead to the specification of the fat-cell primordia (Sections 2.9.2.1 and 2.9.2.2).

Prior to the advent of techniques to mark individual cells, histological studies suggested that fat cells arose in the mesoderm after stage 13 (Poulson, 1950; stages are those of Campos-Ortega and Hartenstein, 1985). The development of *in situ* hybridization and immunohistochemistry protocols to whole-mount embryos has greatly improved the visualization of individual cells and facilitated the description of embryonic tissues, including the fat body (Bier *et al.*, 1989; Wilson *et al.*, 1989; Hartenstein and Jan, 1992; Hoshizaki *et al.*, 1994). The embryonic fat body arises from cells identified at stage 10/11 and is composed of single layers of cells organized into a morphologically distinct tissue; the main or lateral fat body forms a wide bilateral ribbon located between the somatic body-wall muscle and the gut. Extending from the anterior region of the lateral fat body is a collar of fat cells (the ventral commissure) that spans the ventral midline. On the dorsal side of the embryo are fat cells that form a pair of projections extending from the posterior region of the lateral fat body which flank the dorsal vessel (heart) (**Figure 1**) (Hartenstein and Jan, 1992; Hoshizaki *et al.*, 1994; Riechmann *et al.*, 1998; Miller *et al.*, 2002). Upon completion of embryogenesis, the newly emerged larva has a developed fat body.

The first reconstruction of the *D. melanogaster* fat-cell lineage relied upon the expression of the P-element enhancer-trap line [29D] and the known genes, *Adh*, *Drosophila collagen IV* (*DCg1*), and *seven-up* (*svp*) (Hoshizaki *et al.*, 1994). P[29D] is expressed in both the lateral mesoderm and ectoderm. The gene associated with P[29D] has not been identified (Blackburn, 1994; D.K. Hoshizaki, unpublished data). The expression of P[29D] in nine bilateral mesodermal cell clusters in parasegment (PS) 4–12 marks the cells that give rise to the lateral fat body (**Figure 2**). The initial expression of P[29D] at stage 10/11 in mesodermal cell clusters is concurrent with the specification of the progenitors to the somatic body wall muscle (Dohrmann *et al.*, 1990; Michelson *et al.*, 1990; Paterson *et al.*, 1991). By analogy to muscle determination, the P[29D]-expressing cells mark the progenitor fat cells and fat-cell determination is assumed to take place prior to germ band retraction at stage 10/11.

In a manner similar to defining the stages of adipogenesis in the mouse (Ailhaud *et al.*, 1992), the

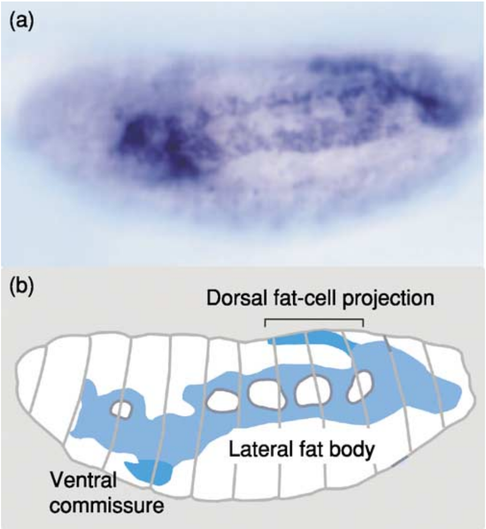

Figure 1 The fat body. (a) Lateral view of a whole-mount stage-16 embryo stained for Serpent (Srp) protein. (b) Corresponding schematic drawing highlighting the fat body domains in blue and segment boundaries in gray. The fat body in a stage-16 embryo is made up of three morphological domains: the lateral fat body, the dorsal fat-cell projections and the ventral commissure. The lateral fat body is made up of a single layer of cells that forms a bilateral ribbon spanning the lateral region of the embryo and is punctuated by stereotypic disruptions that form holes in the tissue. The dorsal fat-cell projections are fused with the posterior-dorsal region of the lateral fat body and extend in the anterior direction, flanking the dorsal vessel. The ventral commissure extends from the anterior-lateral fat body and spans the ventral midline. (Adapted with permission from Miller, J.M., Oligino, T., Pazdera, M., Lopez, A.J., Hoshizaki, D.K., **2002**. Identification of fat-cell enhancer regions in *Drosophila melanogaster*. *Insect Mol. Biol.* *11*, 67–77.)

temporal expression patterns of fat-cell markers, *Adh*, *DCg1*, and *svp*, were used to define the stages of fat-cell differentiation within the developing embryo (**Figure 2**) (Hoshizaki *et al*., 1994). Both *Adh* and *DCg1* are involved in the cellular function of the fat-cell and are expressed in the developing fat body as early as stage 15. The expression of these two genes at stage 15 is used to mark the beginning of terminal fat-cell differentiation, and the fat cells present at this time represent late precursor fat cells. The *svp* gene encodes an orphan steroid hormone receptor (Mlodzik *et al*., 1990) and is expressed in the nine bilateral cell clusters starting at stage 12, before the expression of either *Adh* or *DCg1* (Hoshizaki *et al*., 1994). The early expression of *svp* marks the beginning of fat-cell differentiation in the early precursor fat cells. Loss of *svp* function does not disrupt fat body morphology but does result in the fat-cell-specific loss of *Adh* expression and a reduction in *DCg1* transcripts (Hoshizaki *et al*., 1994). Thus, Svp is likely to function as a transcriptional activator during terminal fat-cell differentiation. Because *svp* expression only overlaps with *Adh* and *DCg1* expression in the fat body, these data provide confirmation that the fat-cell lineage had been correctly identified. The identified nine bilateral cell clusters are part of the fat-cell lineage that gives rise to the lateral fat body (Hoshizaki *et al*., 1994; see below).

In addition to the aforementioned cell clusters that give rise to the lateral fat body, two other groups of cells contribute to the mature fat body. These two groups of cells, the lateral and ventral secondary fat-cell clusters, were identified based on the expression of *A-Box binding factor* gene (*Abf*), also known as *serpent* (*srp*). Abf is a member of the GATA transcription factor family that binds to positive regulatory elements in the larval promoters of all known *Adh* genes (Abel *et al*., 1993). The *Abf* gene was identified as the previously genetically defined gene *srp*, an embryonic gene necessary for germ band retraction, and hemocyte, fat-cell and gut formation (Jurgens *et al*., 1984; Rehorn *et al*., 1996; Sam *et al*., 1996) (Section 2.9.2.2).

A detailed examination of *srp* expression in early embryos confirmed the identification of the lateral fat-body lineage. This study identified the primary fat-cell clusters in PS 4–9, the lateral and ventral secondary fat cells in PS 4–12 and PS 3–11, respectively, and the dorsal fat-cell cluster in PS 13/14 (**Figure 3**) (Riechmann *et al*., 1998). Six of the nine aforementioned bilateral fat-cell clusters that are located in PS 4–9 correspond to the primary fat-cell clusters of Riechmann. The three remaining P[29D] enhancer trap-positive cell clusters in PS 10–12 are likely to correspond to the lateral secondary fat-cell clusters in PS 10–12.

The lateral and ventral secondary fat-cell clusters arise shortly after *srp* expression in the primary fat cells at stage 11 (Riechmann *et al*., 1998). The lateral secondary fat cells in PS 4–12 are composed of metameric repeating cell clusters located immediately adjacent to the position of the primary fat cell location in PS 4–9 (**Figure 3c and d**). The lack of cell markers specific for the lateral secondary fat cells makes it difficult to determine the precise contribution of these cells to the mature fat body, but it is likely that they contribute to the lateral fat body.

The nine cell clusters located in the ventral mesoderm of PS 3–11 make up the ventral secondary fat cells (**Figure 3c and d**). A detailed study of these cells has been carried out using Serpent (Srp) antibodies and a *lacZ* reporter gene driven by a ventral fat-cell enhancer from the promoter region of *srp* (Miller *et al*., 2002). The ventral secondary cell clusters in PS 3–5 give rise to the ventral commissure, which

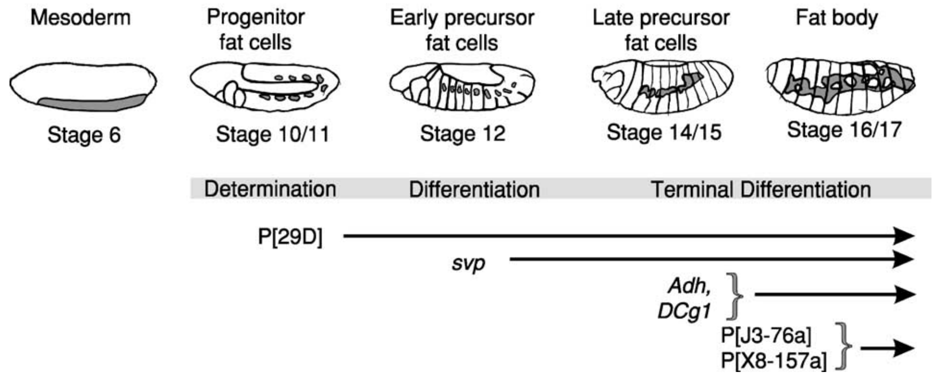

Figure 2 Summary of the fat-cell lineage of the lateral fat body and proposed stages of fat-cell development. The first identified fat-cell lineage described the development of the lateral fat body from nine bilateral clusters of mesodermal cells. The stages of fat-cell development (determination, differentiation, and terminal differentiation) were identified based on the temporal expression of the genes *Adh*, *DCg1*, and *svp* and the enhancer trap lines P[29D], P[J3-76a], and [PX8-157a]. The mesoderm arises from the ventral region of the embryo at stage 6 (shaded area in the stage-6 embryo). The nine bilateral clusters of cells (stage-10, 11 embryo) are represented by the 29D-positive cells which are first detected prior to germ-band retraction during the specification of the mesoderm. The development of the fat body from the nine bilateral clusters of cells is the result of the expansion of these cell clusters and extension of cells arising from the posterior region to form the dorsal fat body (stage-12 embryos). The *svp* gene is transiently expressed in the fat-cell lineage and is first detected at stage 12 in the nine bilateral cells marked by P[29D]. The *svp* gene is expressed before either *Adh* or *DCg1* and is a fat-cell-specific regulator of *Adh* and *DCg1* expression. The expression of *svp* in the precursor fat cells marks the beginning of fat-cell differentiation (stage-12 embryo). The Svp-positive cells at this stage mark the early precursor fat cells. Both *Adh* and *DCg1* are expressed in the developing fat body as early as stage 15 and are involved in the metabolic function of the fat-cell. The initial expression of these genes at stage 15 marks the beginning of terminal fat-cell differentiation and identifies the late precursor fat cells. Finally, the enhancer-trap lines P[J3-76a], and [PX8-157a] are active late in stage 15. (Adapted with permission from Hoshizaki, D.K., Lunz, R., Ghosh, M., Johnson, W., **1995**. Identification of fat-cell enhancer activity in *Drosophila melanogaster* using P-element enhancer traps. *Genome 38*, 497–506.)

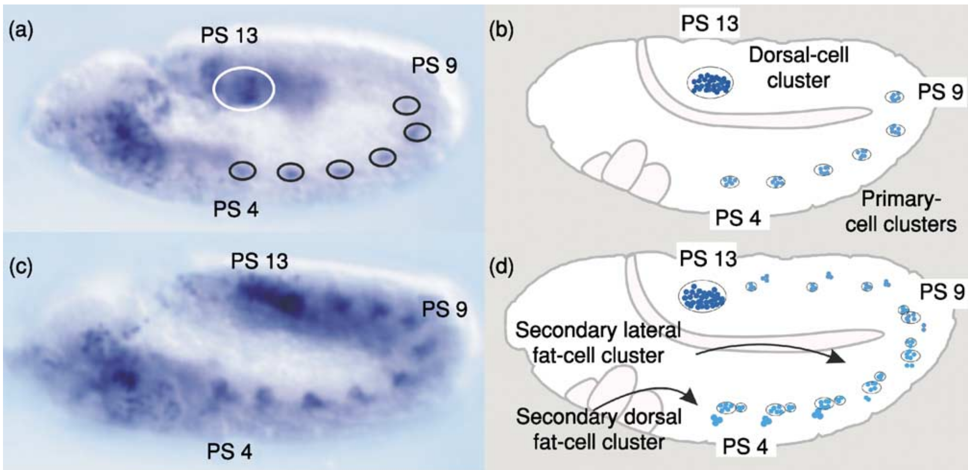

Figure 3 Identification of the precursor cells for the fat body domains. (a, c) Lateral view of a whole-mount embryo stained for Srp. (b, d) Corresponding schematic drawings highlighting precursor fat-cell clusters (blue clusters) and basic outline of the embryo (gray lines). (a, b) Stage-10 embryo. The dorsal fat-cell cluster is located in the dorsal mesoderm of PS 13/14 (large circle in (a) and (b) and the primary fat-cell clusters are located in the lateral mesoderm of PS 4–9 (smaller circles in (a) and (b). (c, d) Stage-11/12 embryo. The secondary ventral fat-cell clusters are located in the ventral mesoderm of PS 3–11 immediately ventral to the primary fat-cell clusters (uncircled blue clusters in (d). A second group of subsidiary precursor fat cells (secondary lateral fat-cell clusters) are located as small cell clusters immediately posterior to the primary cell clusters in PS 4–9 and in the equivalent position in PS 10–12 (small circled blue clusters in (d). (Adapted with permission from Miller, J.M., Oligino, T., Pazdera, M., Lopez, A.J., Hoshizaki, D.K., **2002**. Identification of fat-cell enhancer regions in *Drosophila melanogaster*. *Insect Mol. Biol. 11*, 67–77.)

is composed of two fat-cell bridges (Figure 4). The anterior bridge is derived from the cells in PS 3/4 and is located more internally than the posterior bridge (Figure 4b). The posterior bridge is derived from cells in PS 5 and fuses with the ventralmost cells of the lateral fat body (Figure 4c). Bilateral horns of fat cells extend from the posterior bridge and cross the anterior bridge (Figure 4e). The remaining ventral

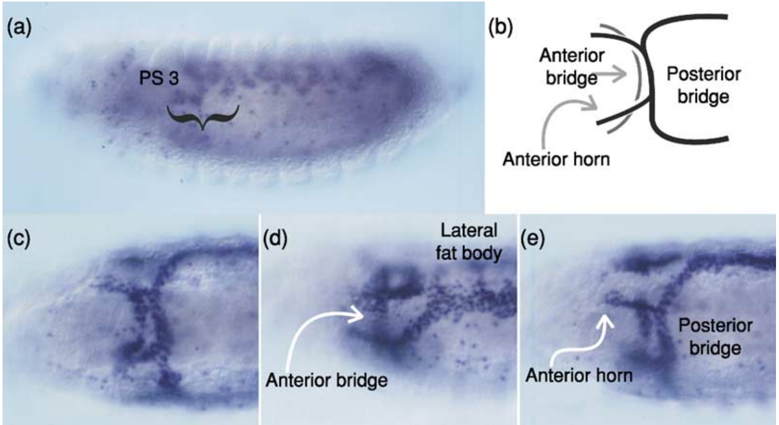

Figure 4 The ventral commissure is composed of two fat-cell bridges. (a) Ventral-lateral view of a stage-13 embryo stained for Srp highlighting the secondary fat-cell clusters in PS 3–5 (bracket). The cell clusters in PS 3 and PS 4 are dorsal to the cluster in PS 5. (b) Schematic drawing of the ventral commissure. The ventral commissure is composed of fat cells that span the ventral midline. The anterior bridge of cells extends from the secondary ventral fat-cell clusters in PS 3 and PS 4 and fuses across the ventral midline. The posterior bridge extends from cells in the bilateral ventral fat-cell cluster in PS 5 and fuses across the ventral midline. (c–d) Ventral and ventral-lateral views of stage-16 embryos stained for Srp. The posterior bridge lies in a more peripheral position within the embryo than the anterior bridge and is a continuation of the ventralmost cells of the lateral fat body. (e) Extending from the posterior bridge are two horns that extend in the anterior direction and cross over the anterior bridge (the second horn is out of the plane of focus). (Adapted with permission from Miller, J.M., Oligino, T., Pazdera, M., Lopez, A.J., Hoshizaki, D.K., **2002**. Identification of fat-cell enhancer regions in *Drosophila melanogaster*. *Insect Mol. Biol. 11*, 67–77.)

secondary fat cells in PS 6–12 populate the ventral edge of the lateral fat body (Miller *et al.*, 2002).

The final group of precursor cells, the dorsal fat cells, lie in PS 13 and part of PS 14. These cells give rise to bilateral projections of fat cells and a portion of the lateral fat body. The projections emerge from the posterior of the lateral fat body and extend in the anterior direction along the dorsal side of the embryo (**Figure 1**) (Riechmann *et al.*, 1998; Miller *et al.*, 2002).

Using a *lacZ* reporter gene driven by a dorsal fat-cell enhancer from the *srp* promoter, the dorsal fat-cell clusters were traced to their final position in the fat-cell projections and the posterior-most cells of the lateral fat body (**Figure 5**) (Miller *et al.*, 2002). Briefly, the dorsal fat-cell projections arise from a bilateral cluster of cells first detected at stage 10 within the dorsal mesoderm (**Figure 5a and b**) (Riechmann *et al.*, 1998; Miller *et al.*, 2002). The dorsal fat-cell cluster spans PS 13 and part of PS 14 (Riechmann *et al.*, 1998; Miller *et al.*, 2002). During germ band retraction, the dorsal fat-cell cluster separates along the dorsoventral axis into two subgroups of cells (**Figure 5e**). Eventually the cells of the dorsal subgroup migrate anteriorly, crossing parasegmental boundaries, to form the bilateral dorsal fat-cell projections, which flank the dorsal vessel (**Figure 5g–i**) (Miller *et al.*, 2002). The cells of the ventral subgroup, together with a small cluster of ventral cells in PS 13, form the posterior-most portion of the lateral fat body (**Figure 5g–j**) (Miller *et al.*, 2002).

2.9.2.1. The Mesoderm and Fat-Cell Lineages

The mature fat body does not have an apparent metameric organization but is derived from cell clusters arranged in a repeating pattern. This observation supports the original suggestion of Rizki and Rizki (1978) that the fat body has a metameric origin. Work from several laboratories has demonstrated that the primordia of the fat body, somatic body wall, visceral and heart muscle, and gonads are derived from segmentally arranged clusters of cells that are dependent upon the subdivision of the mesoderm by pair-rule genes, upon genes involved in segment identity and, in some cases, upon induction events from the ectoderm (Miller, 2002 and references therein).

The mesoderm is derived from ectodermal cells from the ventral-third of the blastoderm and eventually is arranged into two layers, the splanchnopleura or inner layer, and the somatopleura or outer layer (Campos-Ortega and Hartenstein, 1985). Briefly, during gastrulation the presumptive mesoderm cells invaginate into the interior of the embryo to form a furrow along the ventral midline (the ventra1 furrow) and begin an ectoderm-to-mesenchyme transition (Leptin and Grunewald, 1990). Upon completion of invagination, the ventral furrow closes to form the mesodermal tube (germ band; Bate, 1993; Campos-Ortega and Hartenstein, 1997). At stage 8, cells of this internalized mass divide mitotically in the first of three postblastoderm mitoses. During this

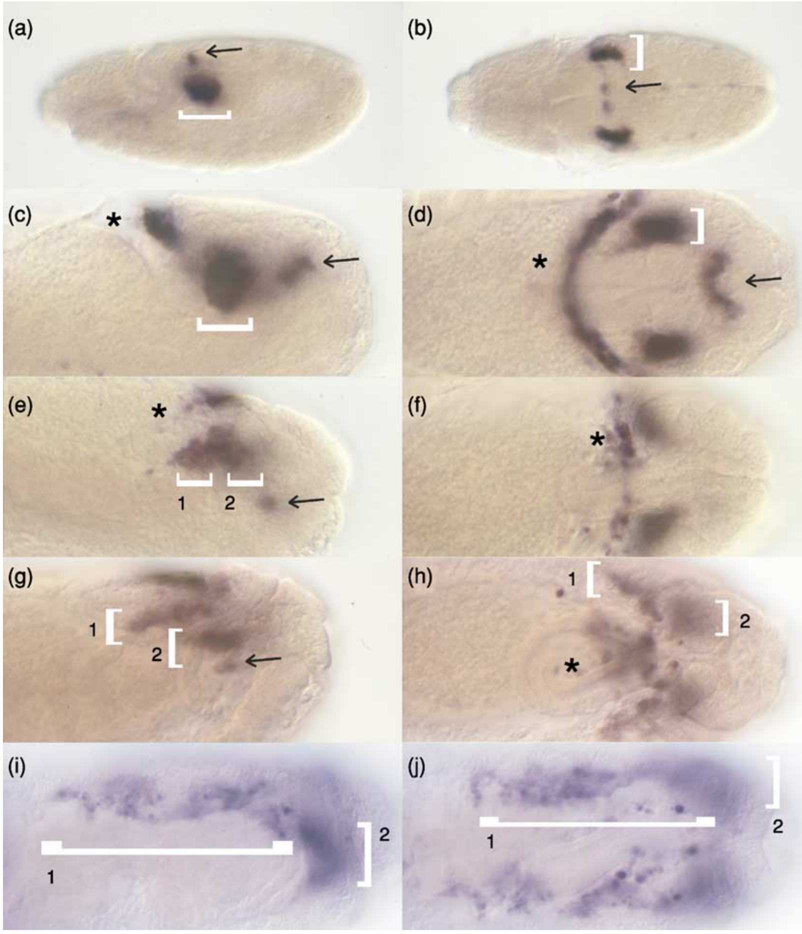

Figure 5 Development of the fat-cell projections. (a) Lateral and (b) dorsal view of a stage-11 embryo stained for β-galactosidase protein. A *lacZ* reporter gene driven by a dorsal fat-cell enhancer was used to follow the development of the dorsal fat-cell cluster. *lacZ* reporter gene activity is detected in the dorsal cell cluster of PS 13 (square bracket) and in a small bilateral ventral cell cluster (arrow). (c) Lateral and (d) dorsal view of a stage-12 embryo. As the germ band retracts, the bilateral ventral clusters of cells in PS 13 fuse across the ventral midline (arrow). *lacZ* reporter gene expression is also detected in the posterior-most amnioserosa cells [star in (c, d)] and in the dorsal fat-cell cluster [bracket in (c, d)]. (e) Lateral and (f) dorsal view of a late stage-12 embryo. As the germ band fully retracts, the dorsal fat-cell cluster begins to separate into two subgroups of cells (square brackets, 1 and 2) and the ventral cluster is now located below the dorsal cell cluster [arrow in (e) and out of the plane of focus in (f)]. *lacZ* reporter gene expression is still detected in the posterior amnioserosa cells (star). (g) Lateral and (h) dorsal view of stage-14 embryo. The dorsal fat-cell cluster has separated into distinct subgroups of cells (square brackets, 1 and 2). The ventral cell cluster is still present (arrow in g). (i) Lateral and (j) dorsal view of a stage 16 embryo. The subgroup of cells from the dorsal fat-cell cluster marked by [bracket 1 in panels (g, h)] forms the dorsal fat-cell projection [bracket 1 in (i, j)] and the second subgroup marked by bracket 2 in (g, h), together with the ventral cell cluster from PS 13 contributes to the posteriormost portion of the lateral fat body. (Reproduced with permission from Miller, J.M., Oligino, T., Pazdera, M., Lopez, A.J., Hoshizaki, D.K., **2002**. Identification of fat-cell enhancer regions in *Drosophila melanogaster*. *Insect Mol. Biol.* *11*, 67–77.)

division, the cells dissociate from one another and abandon all remaining ectodermal characteristics (Bate, 1993; Campos-Ortega and Hartenstein, 1997). The mesoderm forms at stage 9, when the cells elongate and flatten to form a monolayer under the ectoderm. These cells enter the slow phase of germ band extension and undergo the second post-blastoderm mitosis, while still maintaining a monolayer (Campos-Ortega and Hartenstein, 1985; Bate, 1993; Borkowski *et al*., 1995). By stage 10, the first morphological subdivision is detected by a regular fluctuation of *twist* (*twi*) expression along the anterior/posterior axis, which prepatterns the segregation of the somatopleura and the splanchnopleura (Borkowski *et al*., 1995). Mesoderm cells in the high *twi* expression domain appear to adhere strongly to the ectoderm, whereas their immediate neighbors in the low *twi* domain tend to coalesce and segregate inward during the third postblastoderm mitosis to form the splanchnopleura (Borkowski *et al*., 1995; Campos-Ortega and Hartenstein, 1997).

It was originally maintained, based on histological analysis, that fat cells arise from the somatopleura, which also gives rise to the somatic and cardiac musculature (Campos-Ortega and Hartenstein, 1985; see also **Chapter 2.6**). However, based on the location of the fat-cell progenitors (primary fat cells), the fat body primordia is likely to arise from the splanchnopleura (Hoshizaki *et al*., 1994), which also gives rise to the circular visceral muscle precursors (Campos-Ortega and Hartenstein, 1985). This observation is of particular interest because dorsal fat-cell projections and visceral muscle may share an earlier lineage (Miller, 2002; see Section 2.9.2.4).

The early mesoderm is divided by the activity of pair-rule genes into repeating units known as parasegments (Lawrence, 1992; see also **Chapter 1.8**). These same pair-rule genes provide many of the patterning cues necessary for establishing the metameric repeating pattern of the fat-cell primordia. The *srp* gene product is the cell marker used to locate and define the initial appearance of the three groups of fat-cell primordia: the primary, secondary, and dorsal fat-cell clusters (Riechmann *et al*., 1998). As such, *srp* expression in the fat-cell primordia is thought to be important for the final steps of fat-cell specification and commitment to a fat-cell fate (Abel *et al*., 1993; Rehorn *et al*., 1996; Sam *et al*., 1996; Hayes *et al*., 2001). Each group of fat-cell precursors is assigned to a specific functional domain within a parasegment based on its spatial arrangement and genetic requirement for specific pair-rule genes (Riechmann *et al*., 1997, 1998).

The pair-rule genes *even-skipped* (*eve*) and *sloppy-paired* (*slp*) are expressed in stage-11 embryos in an alternating 14-stripe pattern that subdivides each of the parasegments into an *eve* and *slp* functional domain (**Figure 6**) (Frasch *et al*., 1987; Hacker *et al*., 1992). The Eve and Slp functional domains subdivide the parasegment into an anterior and posterior domain, respectively (**Figure 6**); these domains, however, do not correspond to anterior/posterior compartments (Riechmann *et al*., 1997 and appendix therein). The subdivision of each parasegment into these two functional domains best describes the repeating unit that reflects the origins of various mesodermal tissues (Riechmann *et al*., 1997 and

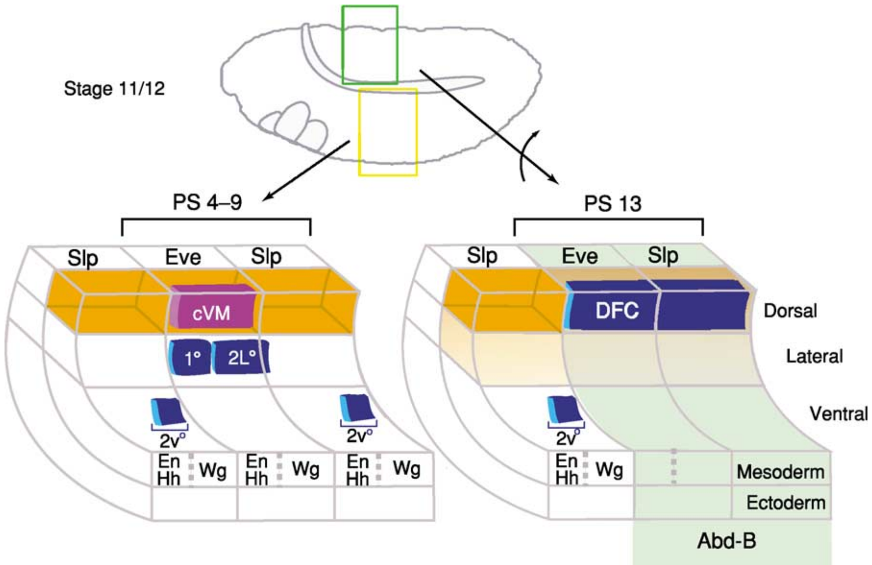

Figure 6 Schematic representation of the ectodermal and mesodermal layers from sections of a stage-11 embryo. The expression pattern of several genes along the anterior/posterior axis is responsible for subdividing the mesoderm into functional domains and subdomains within each parasegment (PS). The genes *eve* and *slp* are expressed in alternative bands in stage-11/12 embryos and functionally subdivide the parasegment (PS). In PS 4–9 the circular visceral muscle precursors (VMc), arise in the dorsal region of each of the Eve domains, while cells in the lateral region of the Eve domain produce two distinct groups of precursor fat cells: the primary fat-cell precursors (1°), which lie within the En, Hh subdomain, and the lateral secondary fat-cell precursors (L2°), which are outside the En, Hh subdomain. A third group of fat-cell precursors cells arises in the lateral region of the Slp within the Wg subdomain. In PS 13, *en* and *hh* are no longer expressed in the anterior compartment of the Eve domain. The presence of Abd-B protein in PS 13 represses precursor fat-cell formation in the lateral region, and in the dorsal region of PS 13 Abd-B simultaneously represses cVM formation and induces fat-cell formation. These precursor fat cells form the dorsal fat-cell cluster (DFC). (Based on data from Riechmann, V., Rehorn, K.P., Reuter, R., Leptin, M., **1998**. The genetic control of the distinction between fat body and gonadal mesoderm in *Drosophila*. *Development 125*, 713–723, and references therein, adapted with permission from Miller, J.M., **2002** Analysis of the cell-specific expression of the *serpent* gene and its role as a cell-fate switch in *Drosophila melanogaster*. Ph.D. thesis, University of Nevada, Las Vegas.)

appendix therein). The primary fat-cell clusters reside in the lateral mesoderm within the *eve* domain of PS 4–9 and are restricted to the anterior region of the *eve* domain by the expression of *engrailed* (*en*) and *hedgehog* (*hh*) (**Figure 6**) (Riechmann *et al.*, 1998).

Shortly after the emergence of the primary fat cells, two sets of secondary fat-cell clusters arise in a metameric pattern (**Figure 3**) (Riechmann *et al.*, 1998). The lateral secondary fat cells arise in the *wingless* (*wg*) subdomain of the Eve domain of PS 4–12 (**Figure 6**). These cell clusters are located immediately posteriorly of the position of the primary cell clusters and outside of the *en* and *hh* subdomain, and may extend into the *slp*-expression domain (Riechmann *et al.*, 1998). The third group of fat cells, the secondary ventral fat-cell clusters, are under the control of *wg* within the Slp domain, but it is likely that the reorganization of the ventral mesoderm brings about the placement of the ventral fat-cell cluster to the border of the Eve and Slp domain (Riechmann *et al.*, 1998). The *slp* gene encodes a forkhead domain transcription factor that negatively regulates *eve* activity (Hacker *et al.*, 1992). Thus, the ventral secondary fat-cell clusters depend upon positional information that is incompatible with the specification of the primary fat-cell clusters, which requires *eve* (and *en*/*hh*) activity. The final group of fat cells, the dorsal fat-cell cluster, resides in the dorsal mesoderm and spans the entire PS 13 and the Eve domain of PS 14 (**Figure 6**) (Riechmann *et al.*, 1998; Miller *et al.*, 2002).

Along the anterior/posterior axis, the presence or absence of groups of fat-cell clusters varies according to parasegment identity. It is likely that segment identity genes, such as the homeotic genes of the *Bithorax Complex,* further influence the specific nature of specified cells (Lawrence, 1985; Hooper, 1986; Bate, 1990; Bienz, 1994; Capovilla *et al.*, 1994; Michelson, 1994). Target genes for various homeotic genes have been identified such as *scabrous* (*sca*; Graba *et al.*,1992) and *decapentaplegic* (*dpp*; Immerglück *et al.,* 1990). In most cases, however, these target genes are involved in the final steps of cell or tissue differentiation and are removed from the initial cell specification steps. *srp* is involved in fat-cell specification and is an *in vitro* target of the homeotic transcription factor Ultrabithorax (Ubx) (Mastick *et al.*, 1995). *Ubx* is expressed in the mesoderm of PS 6–12 (White and Wilcox, 1984; Akam and Martinez-Arias, 1985) and is not expressed in the parasegments that give rise to the dorsal fat-cell projection (PS 13/14) or the ventral commissure (PS 3–5). Loss of *Ubx* activity has little effect on the formation of the dorsal projections, but misexpression of *Ubx* throughout the mesoderm reduces the dorsal projections to single rows of cells (**Figure 7**) (Miller *et al.*, 2002).

Ubx represses the formation of the ventral commissure (Miller *et al.*, 2002). The secondary ventral fat-cells in PS 3–5 lie outside the Ubx domain. Loss of *Ubx* activity results in strong derepression of *srp* within the secondary ventral fat-cell clusters in PS 6–12 and the formation of an ectopic fat-cell bridge, which arises from PS 6 (**Figure 7**) (Mastick *et al.*, 1995; Miller *et al.*, 2002). Furthermore, misexpression of *Ubx* throughout the mesoderm is sufficient

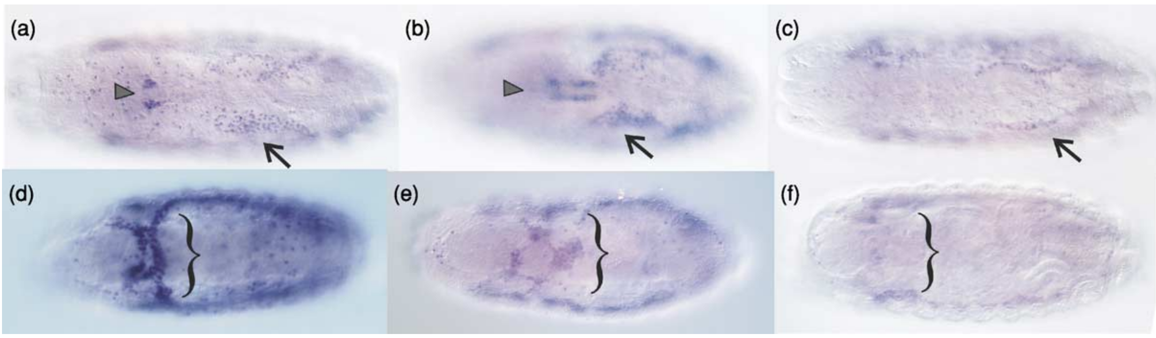

Figure 7 *Ubx* is involved in the formation of the dorsal fat-cell projection and ventral commissure. (a) Dorsal view of wild-type, (b) *Ubx* mutant, and (c) *twi-GAL4;UAS-Ubx* stage-16 embryos stained for Srp protein. (a) Wild-type dorsal fat-cell projection (arrow) and lymph glands (arrowhead). (b) Loss of *Ubx* has little or no effect on the number of cells contributing to the dorsal fat-cell projection (arrow). The lymph glands have hypertrophied (arrowhead) as previously described by Mastick *et al.* (1995). (c) In the *twi-GAL4;UAS-Ubx* embryo, *Ubx* is misexpressed throughout the mesoderm. Misexpression of *Ubx* reduces the width of the dorsal fat-cell projections (arrow) to 1–2 cells, compared to the normal 6–8-cell width, and causes the loss of the lymph glands. Ventral view of stage-16 wild-type (d), *Ubx* mutant (e), and *twi-GAL4;UAS-Ubx* (f) embryos stained for Srp protein. (d) Wild-type ventral commissure (bracket). (e) Loss of *Ubx* results in the formation of an ectopic ventral commissure (bracket) from PS 6, while (f) misexpression of *Ubx* throughout the mesoderm represses the formation of the ventral commissure. Bracket marks the loss of the ventral commissure. (Adapted with permission from Miller, J.M., Oligino, T., Pazdera, M., Lopez, A.J., Hoshizaki, D.K., **2002**. Identification of fat-cell enhancer regions in *Drosophila melanogaster*. *Insect Mol. Biol.* *11*, 67–77.)

to completely suppress the formation of the endogenous ventral commissure (**Figure 7**) (Miller *et al.*, 2002). The loss- and gain-of-function data indicate that Ubx represses the formation of two fat-body domains: the ventral commissure and the dorsal projections. These data are in contrast to the *in vitro* data, which indicate *srp* is a direct target of Ubx and therefore suggest that *Ubx* might have a role in fat-cell specification through the control of *srp*. It is likely that the role of *Ubx* in the repression of the ventral commissure and the dorsal projections is the result of segment identity changes through the action of a hierarchy of genes rather than through direct activation of *srp*.

In contrast to *Ubx*, the other two genes of the Bithorax complex, *abdominal A* (*abd-A*) and *Abdominal B* (*Abd-B*), have a role in the specification of fat cells and are likely to be directly involved in the transcriptional control of *srp*. *abd-A* is expressed in PS 10–12 and represses the formation of the primary fat-cell clusters in these parasegments (Moore *et al.*, 1998). In the absence of Abd-B, primary fat-cell clusters are induced in PS 10–12 and replace the somatic gonadal precursors (Moore *et al.*, 1998; see also Section 2.9.2.3).

Abd-B's role in fat-cell specification is complicated and context dependent. The dorsal fat-cell cluster arises in PS 13/14 within the mesodermal expression domain of the morphogenic (m) isoform of the homeotic gene *Abd-B* (Akam and Martinez-Arias, 1985; Casanova *et al.*, 1986). *Abd-B* is expressed at its highest levels in PS 13 (**Figure 6**), and is present in declining levels in PS 11–12 (Delorenzi and Bienz, 1990). Loss- and gain-of-function experiments have demonstrated that high levels of *Abd-B* expression are both necessary and sufficient for formation of the dorsal fat-cell cluster *within* the dorsal mesoderm (Miller, 2002; see Section 2.9.2.4 for details). In the absence of *Abd-B* gene function, the dorsal fat-cell cluster in PS 13/14 is not specified (Riechman *et al.*, 1998; Miller, 2002; see also Section 2.9.2.4) while misexpression of *Abd-B* in parasegments anterior to PS 13 results in the induction of a stereotypic repeating pattern of dorsal fat-cell clusters in the dorsal mesoderm (**Figure 8**) (Miller, 2002; see also Section 2.9.2.4). Outside the dorsal mesoderm, in the lateral and ventral mesoderm, high levels of Abd-B repress formation of the primary and secondary fat cells in the lateral and ventral mesoderm. Thus, Abd-B induces fat-cell formation in the dorsal mesoderm and represses fat-cell formation in the lateral and ventral mesoderm. As noted, *Abd-B* is also expressed in PS 11 and 12, albeit at lower levels than in PS 13. In PS 10–12 of wild-type embryos, the secondary fat-cell clusters in the lateral mesoderm are present, but the primary fat-cell clusters are missing. In the absence of Abd-B, a putative primary fat-cell cluster appears in PS 12 (Moore *et al.*, 1998). Thus, the titer of Abd-B also appears to play a role in the induction/repression of the fat cells along the dorsal ventral axis of the mesoderm.

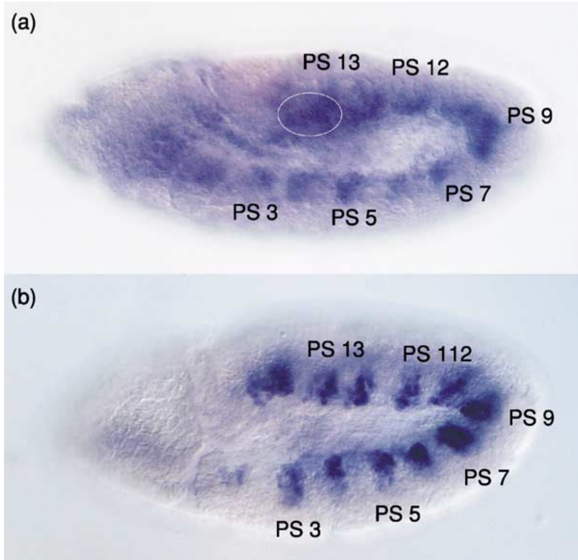

Figure 8 Misexpression of *Abd-B* in the mesoderm results in the serial duplication of the dorsal fat-cell cluster. (a) *twi-GAL4;UAS-Abd-B* embryo where *Abd-B* is misexpressed throughout the mesoderm. Embryo is stained for Srp protein, and reveals the presence of the DFC cluster in PS 13 (circle) and ectopic *srp*-expressing clusters in the posterior compartment of PS 2–12 within the dorsal mesoderm. Primary and secondary fat-cell clusters are not detected. In (b), the *twi-GAL4;UAS-Abd-B* embryo carries the dorsal fat-cell *lacZ* reporter gene and is stained for β-galactosidase protein. The expression pattern of β-galactosidase protein recapitulates the ectopic Srp-expression pattern in (a) and, thus, the ectopic *srp*-expressing cells are derived from ectopic dorsal fat-cell clusters. (Adapted with permission from Miller, J.M., **2002**. Analysis of the cell-specific expression of the *serpent* gene and its role as a cell-fate switch in *Drosophila melanogaster*. Ph.D. Thesis, University of Nevada, Las Vegas.)

In the aforementioned experiments, the presence or absence of fat-cell clusters was determined by *srp* gene expression. Thus, Abd-B is a positive regulator of *srp* in the dorsal mesoderm and a negative regulator of *srp* in the lateral/ventral mesoderm. The opposing response of *srp* to Abd-B reflects fundamental patterning differences between the dorsal and lateral/ventral mesoderm. The dorsal mesoderm is defined by *decapentaplegic* (*dpp*)-maintained *tinman* (*tin*) activity. *tin* is an NK homeodomain protein-encoding gene that is expressed in three phases during embryonic development (Kim and Nirenberg, 1989). Initially, *tin* is expressed in a pan-mesodermal fashion. In the second phase, *dpp* activity in the ectoderm induces the continued expression of *tin* in the

underlying dorsal region of the mesoderm, while *tin* expression in the ventral and lateral mesoderm declines. In this second phase, *tin* defines the dorsal mesoderm. In the third phase, *tin* expression is restricted to and marks the precursor to the heart (Azpiazu and Frasch, 1993; Bodmer, 1993; Yin and Frasch, 1998).

Moore *et al*. (1998) suggested that early *tin* expression is responsible for the specification of fat cells, based on a comparison of *tin* and *dpp* mutant phenotypes. Because the second phase of *tin* expression is dependent upon *dpp*, this comparison can distinguish between the requirement of the first or second phase of *tin* actvity on fat-cell specification. Based upon an apparent increase in fat-cell number in *dpp* mutants compared to *tin* mutants, it was concluded that the initial phase of *tin* expression is important for the specification of fat cells. However, because of the gross developmental defects associated with the loss of *dpp*, it is difficult to estimate the change in the number of fat cells (Moore *et al*., 1998).

Using a *lacZ* reporter gene driven by a dorsal fat-cell enhancer from the *srp* promoter, Miller *et al*. (2002) re-examined the role of *tin* and *dpp* in the specification of one fat-cell domain, the dorsal fat-cell projections. In embryos in which *dpp* is misexpressed throughout the mesoderm, the expression of *tin* persists in the lateral and ventral mesoderm. In these embryos, the dorsal fat-cell cluster is expanded to fill most of PS 13 by extending into the lateral and ventral regions (**Figure 9**). In contrast, in *dpp* mutants (and *tin* mutants), few, if any, dorsal fat cells are detected (**Figure 9**) and, concomitantly, the dorsal fat-cell projections (and the posterior-most cells of the lateral fat body) are absent. Thus, the specification of the dorsal fat-cell cluster depends upon the second phase of *tin* expression, which is responsible for the formation of the dorsal mesoderm (Miller *et al*., 2002). It has yet to be determined whether Tin or downstream factors intrinsic to the dorsal mesoderm are direct transcriptional activators of *srp*. To summarize, the role of *Abd-B* gene expression in the specification of the different precursor fat cells is integrated with both positional information and the concentrations of *Abd-B* protein.

2.9.2.2. Role of Serpent in Fat-Cell Specification

Key to the specification, differentiation, and maintenance of fat cells in *D. melanogaster* is the activity of *srp*. Although *srp* is expressed in derivatives of all three germ layers, within the trunk mesoderm *srp* is expressed in precursor fat cells and is the earliest identified fat-cell gene (Abel *et al*., 1993; Rehorn *et al*., 1996; Sam *et al*., 1996). Srp is a key regulator of fat-cell development. Loss of *srp* results in the inability to maintain the progenitor fat cells of the lateral fat body and the loss of all mature fat cells (Rehorn *et al*., 1996; Sam *et al*., 1996), whereas misexpression of *srp* in the mesoderm is sufficient to induce ectopic fat cells and to disrupt the specification/differentiation of the somatic and visceral muscle and the gonadal mesoderm (Hayes *et al*., 2001). These lines of evidence suggest that *srp* can operate to various degrees as a cell-type determining gene within the mesoderm.

Srp is a member of the GATA transcription factor family, and is involved in cell-fate specification and differentiation (Ramain *et al*., 1993; Winick *et al*.,

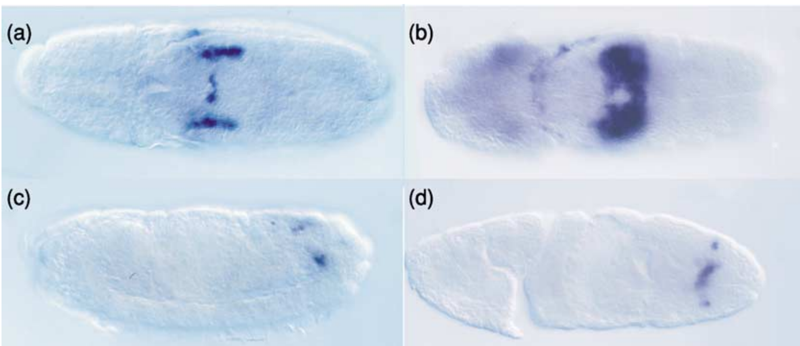

Figure 9 Specification of the dorsal cell cluster requires the formation of the dorsal mesoderm. (a) Stage-11 wild-type embryo carrying the *lacZ* dorsal fat-cell reporter gene of Miller *et al*. (2002): β-galactosidase staining marks the dorsal fat-cell cluster. (b) Stage-11 *twi-GAL4*;*UAS-dpp* embryo carrying the *lacZ* dorsal fat-cell reporter gene stained for β-galactosidase protein: *dpp* is misexpressed throughout the mesoderm and causes the ventral expansion of the dorsal fat-cell cluster to occupy most of PS 13. (c) Stage-13 *tin* and stage-12 *dpp* mutant (d) embryos carrying the *lacZ* dorsal fat-cell reporter: the dorsal fat-cell cluster consists of a few cells in both mutant backgrounds revealed by the loss of *lacZ*-expressing cells (c, d) and results in the loss of the fat-cell projections (and posterior-most cells of the lateral fat body). (Adapted with permission from Miller, J.M., Oligino, T., Pazdera, M., Lopez, A.J., Hoshizaki, D.K. **2002**. Identification of fat-cell enhancer regions in *Drosophila melanogaster. Insect Mol. Biol. 11*, 67–77.)

1993; Harigae *et al.*, 1998; Gajewski *et al.*, 1999). It was initially identified as a transcriptional activator of *Adh* in fat cells (Abel *et al.*, 1993) and was subsequently shown to have a role in fat-cell determination and differentiation (Rehorn *et al.*, 1996; Sam *et al.*, 1996; Moore *et al.*, 1998; Riechmann *et al.*, 1998; Hayes *et al.*, 2001). In addition, *srp* is also involved in the differentiation and morphogenesis of the gut (Reuter, 1994; Rehorn *et al.*, 1996; Murakami *et al.*, 1999), germband retraction (Frank and Rushlow, 1996), hematopoiesis (Rehorn *et al.*, 1996; Lebestky *et al.*, 2000, 2003; Fossett *et al.*, 2001; Waltzer *et al.*, 2002), and larval fat-cell specific expression (Brodu *et al.*, 1999, 2001; Petersen *et al.*, 1999; Tingvall *et al.*, 2001).

Based on genetic studies, *srp* gene expression is also necessary for maintaining fat-cell identity in the lateral fat body (Sam *et al.*, 1996). In transcript- and protein-expressing *srp* loss-of-function mutants, *srp* gene-expressing cells are readily detected in the position of the fat-cell precursors, but later these cells appear to undergo apoptosis (Sam *et al.*, 1996). The loss of *srp* function, however, does not prevent early expression of the enhancer trap line [29D] in the progenitor fat cells that give rise to the lateral fat body (Sam *et al.*, 1996). Thus, *srp* appears *not* to be necessary for specification of the lateral fat body *per se*, but is necessary for the maintenance of progenitor fat-cell identity.

Experiments based on deregulated expression of *srp* reveal that *srp* can also induce embryonic fat-cell formation and disrupt development of other mesodermal tissues (Hayes *et al.*, 2001). Misexpression of *srp* throughout the mesoderm results in an increase in the number of fat cells and an expansion of the lateral fat body (**Figure 10**) (Hayes *et al.*, 2001).

The ability of *srp* to induce fat-cell formation is likely to be cell autonomous and to depend upon mesodermal factors. Misexpression of *srp* in the ectoderm is not sufficient to induce the fat-cell markers *Adh* or *DCg1* in the ectoderm, nor does it alter the normal development or morphology of the lateral fat body (Hayes *et al.*, 2001). The capacity of *srp* to generate fat cells is also dependent upon other factors, because premature expression of *srp* does not result in premature expression of fat-cell genes (Hayes *et al.*, 2001). It is likely that the preservation of the correct temporal sequence in fat-body development reflects the dependence of *srp* on the expression of temporally restricted mesodermal factors.

The ectopic fat cells generated by the misexpression of *srp* in the mesoderm are not derived from the endogenous fat-cell lineage (Hayes *et al.*, 2001). Early expression of the fat-cell marker P[29D] is independent of *srp* (Sam *et al.*, 1996) and, thus, P[29D] was used as a cell marker to examine the origin of the ectopic fat cells. The number and organization of the fat cells marked by P[29D] appear normal in the embryos, even though these embryos have an increased number of ectopic fat cells, which express several fat-cell markers, e.g., *Adh* and *DCg1* (Hayes *et al.*, 2001). Thus, the increase in fat cells is not due to hyper-proliferation of endogenous fat-cell lineage, although the possibility that the ectopic fat cells originate from the secondary fat-cell clusters, which are not labeled by P[29D], has not been eliminated.

The misexpression of *srp* in the mesoderm also results in the loss or disruption of the gonadal mesoderm, visceral muscle, and body-wall muscle (Hayes *et al.*, 2001). The body-wall muscles are syncytia derived from single founder muscle cells, which serve as focal points for fusion with the surrounding myoblasts (Rushton *et al.*, 1995; Knirr *et al.*, 1999; see **Chapter 2.1**). Misexpression of *srp* in the mesoderm results in the loss of both *nautilus* (*nau*)-expressing and *S59*-expressing founder muscle cells. Consistent with this loss is a dramatic decrease

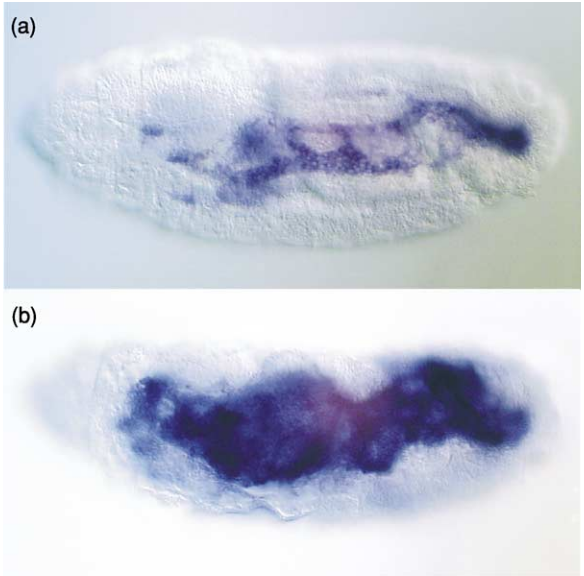

Figure 10 Misexpression of *srp* in the mesoderm leads to expansion of the fat body. (a, b) Stage-16 embryos stained for *Adh* mRNA. (a) Lateral view of a wild-type embryo. The lateral fat body consists of a ribbon-like band of cells with multiple disruptions or holes. Figure 11 Misexpression of *srp* in the mesoderm leads to loss of somatic musculature. (a–d) Lateral views of stage-16 embryos stained for *Tropomyosin 1* (*Tm1*) mRNA. (a) In a wild-type embryo, *Tm1* (dark blue) is expressed in the somatic body-wall fibers. (b) In *twist-GAL4*;*UAS-srp* embryo, where *srp* is misexpressed throughout the mesoderm, most somatic muscle fibers are missing. (c, d) Higher magnifications of (a, b) respectively. (Reproduced with permission from Hayes, S.A., Miller, J.M., Hoshizaki, D.K., **2001**. *serpent*, a GATA-like transcription factor gene, induces fat-cell development in *Drosophila melanogaster*. *Development 128*, 1193–1200; © The Company of Biologists Ltd.)

in the number of muscle fibers (Figure 11). The few remaining muscle fibers are mono- and bi-nucleated and their number and location varies from embryo to embryo (Hayes *et al*., 2001). The correlation between the loss of body-wall muscle and the gain of ectopic fat cells presents an attractive possibility that the loss of founder muscle cells and myoblasts is due to the conversion of their respective primordia to a fat-cell fate. The role of *srp* in the disruption of gonads and visceral muscle formation is discussed below.

2.9.2.3. Fat Body Versus Gonads

The subdivision of the mesoderm by pair-rule genes provides many of the patterning cues necessary for establishing the fat-cell primordia. The expression of *srp* in the fat-cell primordia is important for the final steps in the commitment to a fat-cell fate and fat-cell specification. Thus, *srp* is likely to be a target of multiple transcriptional regulators that together provide unique compound positional cues associated with and according to the stereotypic location of individual fat-cell clusters. It is likely that other cell-specifying genes also respond to unique combinations of positional cues. Several lines of evidence suggest that the primary fat cells in PS 4–9 and the somatic gonadal precursors (SGPs) in PS 10–12 share a common precursor or are derived from a common pool of cells that can give rise to either cell type (Moore *et al*., 1998; Riechmann *et al*., 1998; Hayes *et al*., 2001). The SGPs give rise to the gonadal mesoderm, which makes up the somatic component of the gonads. The primary fat-cell clusters (in PS 4–12) and the SGPs (in PS 10–12) both

arise from cells in the same dorsoventral plane within the *eve* domain of their respective parasegments (**Figure 6**). These cells may represent common precursors that lie within PS 4–12 in a metameric repeating pattern. Based on genetic studies, *srp* activity in PS 4–9 directs formation of the primary fat cells, while the absence of *srp* expression in PS 10–12 allows SGP formation (Moore *et al.*, 1998; Riechmann *et al.*, 1998).

The repression of *srp* in the lateral mesoderm of PS 10–12 is mediated by *abd-A*, a homeotic gene involved in segment identity. Within the mesoderm, *abd-A* is expressed in PS 10–12 (Karch *et al.*, 1990). In *abd-A* loss-of-function mutants, the SGPs in PS 10–12 are absent, based on the lack of *zinc finger homeobox factor 1* (*zfh-1*) gene expression, and are replaced by *srp*-expressing cells (Moore *et al.*, 1998). ZFH-1 is a regulator of gonadal mesoderm development (Broihier *et al.*, 1998). In *abd-A* and *srp* double mutants, the expression pattern of *clift* (*cli*) and *412*, two SGP markers, is expanded to cells located in the equivalent position of the primary fat-cell clusters (Brookman *et al.*, 1992; Boyle *et al.*, 1997; Moore *et al.*, 1998). Thus, the apparent default fate of the common precursor is to become SGP, while *abd-A*'s role is to repress *srp* which, in turn, allows SGP formation (Moore *et al.*, 1998). The choice between primary fat cells and SGPs appears to rely upon *srp* activity that induces fat-cell formation in the common precursor, thereby preventing SGP specification.

This model predicts that forced expression of *srp* in the mesoderm should induce primary fat cells in PS 10–12 and repress SGP formation. Srp is capable of inducing fat-cell formation, as demonstrated in embryos where *srp* is misexpressed throughout the mesoderm (Hayes *et al.*, 2001). While on the surface these results favor the common precursor model, the forced expression of *srp* in the mesoderm does *not* affect the specification of the SGPs; rather, the SGPs fail to migrate and coalescence to form the gonads (**Figure 12**) (Hayes *et al.*, 2001). In wild-type embryos, *cli* is necessary for the migration and coalescence of the SGPs to form the gonads, but *not* for the

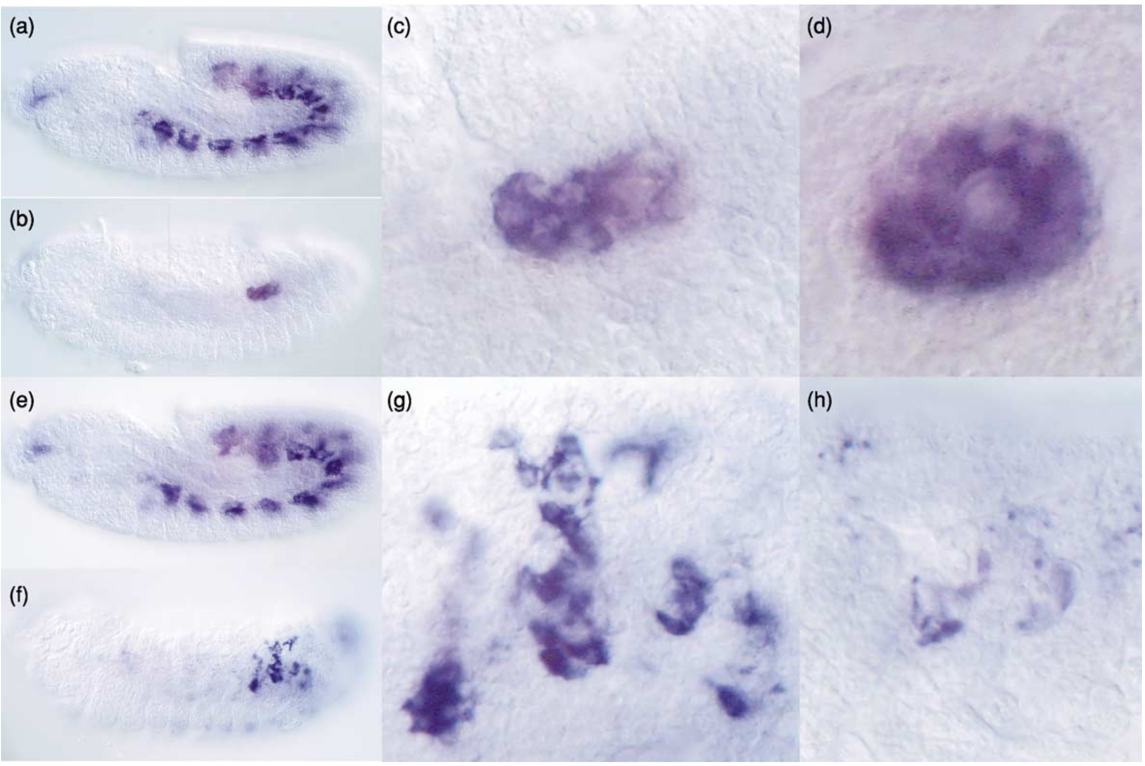

Figure 12 Misexpression of *srp* in the mesoderm leads to a disruption of the final stages of gonad formation. (a–d) Lateral view of wild type and (e, f) *twist-GAL4;UAS-srp* embryos stained for 412 mRNA. In *twist-GAL4;UAS-srp* embryos, *srp* is misexpressed throughout the mesoderm. In stage-12 wild-type embryos (a) and mutant embryos (e) *412* is expressed in clusters of cells in PS 2–12. In stage-14 wild type (b, c) and experimental (f, g) embryos *412* expression persists, in the SGPs. (c) and (g) are higher magnifications of (b) and (f), respectively. By stage 16, *412* expression marks the mature gonad in the wild-type embryo (d), while in the mutant embryos few 412-positive cells are detected (h). (Reproduced with permission from Hayes, S.A., Miller, J.M., Hoshizaki, D.K., **2001**. *serpent*, a GATA-like transcription factor gene, induces fat-cell development in *Drosophila melanogaster*. *Development 128*, 1193–1200; © The Company of Biologists Ltd.)

specification of the SGPs (Boyle *et al*., 1997). *cli* activity is also necessary for *412* expression (Boyle *et al*., 1997). In the mutant embryos where *srp* is misexpressed throughout the mesoderm, *cli* but *not 412* expression is absent in the SGPs (Hayes *et al*., 2001). This seemingly paradoxical result is best explained if the entire expression pattern of *cli* is taken into consideration. In the experimental embryos, the early expression pattern of *cli* is similar to wild type; *cli* protein is readily detected throughout the mesoderm and by early-stage 11 is lost in most mesodermal cells. At late-stage 11, *cli* expression is detected in the lateral muscle precursors as well as in the ectoderm (as seen in wild-type embryos), but no wild-type expression is observed in the SGPs (Hayes *et al*., 2001). In these same experimental embryos, *412* expression is normal; the metameric repeating expression of *412* is readily detected, and *412* undergoes the normal decline in PS 2–9 and continues to be expressed in the SGPs (PS 10–12) (Hayes *et al*., 2001). The occurrence of normal *412* expression in the experimental embryos suggests that early pan-mesoderm expression of *cli* at stage 10 is responsible for initiating *412* expression. Later in embryonic development, the *412*-expressing SGPs do not coalesce into a precursor gonad but remain scattered in the posterior region of the embryo (**Figure 12**) (Hayes *et al*., 2001). The absence of late *cli* expression in the SGPs of the mutant embryos is consistent with the inability of the SGPs to migrate and coalesce to form the gonads (Boyle *et al*., 1997).

An alternative model brought forth by Hayes *et al*. (2001) suggests that the precursors to the SGPs and the fat cells are derived from independent but closely associated groups of cells. Positional cues within each parasegment might specify which group will differentiate and be maintained. This model, in general terms, is analogous to the interaction between the mammalian Wolffian and Müllerian ducts (Hughes, 2001). In early mammalian development, before gonadal differentiation, both ducts are present. In females, the Müllerian duct develops into the oviduct while the Wolffian duct degenerates. In males, the production of Müllerian inhibition substance in the testes causes the degeneration of the Müllerian duct, while the Wolffian duct develops into the *vas deferens* (Higgins *et al*., 1989). In this alternative model, the absence of *srp* activity in PS 10–12 allows the SGPs to be specified and differentiate, while the fat-cell precursors are not maintained. Furthermore, in PS 4–12, *srp* activity allows the proliferation and maintenance of the precursor fat cells, while the SGPs do not differentiate. A role for *srp* in the maintenance of the fat-cell lineage has been previously suggested by Sam *et al*. (1996), who demonstrated that progenitor fat cells were present in *srp* mutant embryos. In the protein null mutant, srp^{6G45}, progenitor fat cells were identified by the expression of the P[29D] enhancer trap, and in the missense mutant srp^{9L06}, progenitor fat cells were detected by both P[29D] expression and immunohistochemical staining using an Srp antibody. In both mutant backgrounds the fat cells are absent by stage 15. Loss of the developing fat cells is likely to be due to programmed cell death based on the increase in apoptotic cell death in the location of the developing cells (**Figure 7** in Sam *et al*., 1996).

2.9.2.4. Fat Body Versus Visceral Muscle

The fat-cell projections arise from bilateral dorsal fat-cell clusters located within the dorsal portion of PS 13 and part of PS 14 (Riechmann *et al*., 1998; Miller *et al*., 2002). On the dorsoventral axis, the dorsal fat-cell clusters align with the precursors to the circular visceral mesoderm (cVM; **Figure 6**) in PS 3–12 (Azpiazu and Frasch, 1993; Riechmann *et al*., 1998; San Martin *et al*., 2001; Miller *et al*., 2002). Both of these cell types depend upon the formation of the dorsal mesoderm (Staehling-Hampton *et al*., 1994; Frasch, 1995; Riechmann *et al*., 1998; Miller *et al*., 2002). Recent studies on *Abd-B's* role in fat-cell specification suggest that the dorsal fat-cell projection and circular visceral musculature are derived from a pool of equivalent cells (Miller, 2002). As previously described, in the absence of *Abd-B* function, the *srp*-expressing cells that make up the dorsal fat-cell clusters are absent (Riechmann *et al*., 1998; Miller *et al*., 2002). In embryos in which *Abd-B* is misexpressed throughout the mesoderm, the primary and secondary fat cells are absent, and the only *srp*-expressing cell clusters, are serially duplicated in the dorsal mesoderm (**Figure 8**). These cells are duplicated dorsal fat-cell clusters, based on the expression of a reporter gene driven by a dorsal fat-cell enhancer (Miller, 2002). These data suggest that *Abd-B* is sufficient to activate *srp* and induce formation of a dorsal fat-cell cluster within the dorsal mesoderm.

The arrangement of the serially duplicated dorsal fat-cell clusters is reminiscent of the spatial pattern of the precursors to the cVM cells. The cVM precursors are derived from the dorsal mesoderm within the Eve domain of PS 2–12 (**Figure 6**) and are marked by *bagpipe* (*bap*) (Azpiazu and Frasch, 1993; Riechmann *et al*., 1997; San Martin *et al*., 2001). The *bap* gene is expressed in, and is necessary for, the formation of 11 cVM precursor cell clusters

(Azpiazu and Frasch, 1993). These clusters give rise to the circular visceral muscles that surround the gut and are necessary for the sterotypic constrictions that model the gut in mature embryos (Azpiazu and Frasch, 1993; San Martin *et al.*, 2001). In embryos where *Abd-B* is misexpressed throughout the mesoderm, *bap* expression is absent in the cVM (**Figure 13**) (Miller, 2002) and the gut is distended and missing its characteristic constrictions (D.K. Hoshizaki and J.M. Miller, unpublished data). This gut phenotype is similar to a loss-of-function *bap* mutant phenotype in which the circularly visceral muscles are absent. These data suggest that *Abd-B* controls a developmental switch between the dorsal fat-cell cluster and the cVM precursors.

Consistent with the common precursor model is the observation that in an *Abd-B* mutant embryo there is an ectopic cluster of cVM precursors in PS 13 (**Figure 13c**). These data suggest that *Abd-B*'s normal role is to simultaneously induce dorsal fat-cell formation and repress cVM formation in PS 13. Thus, in wild-type embryos, the absence or reduced levels of Abd-B in the anterior segments (PS 2–12), allows *bap* expression and the formation of the cVM precursors, while high levels of Abd-B in PS 13 induce *srp* expression in the dorsal mesoderm and the specification of a dorsal fat-cell cluster.

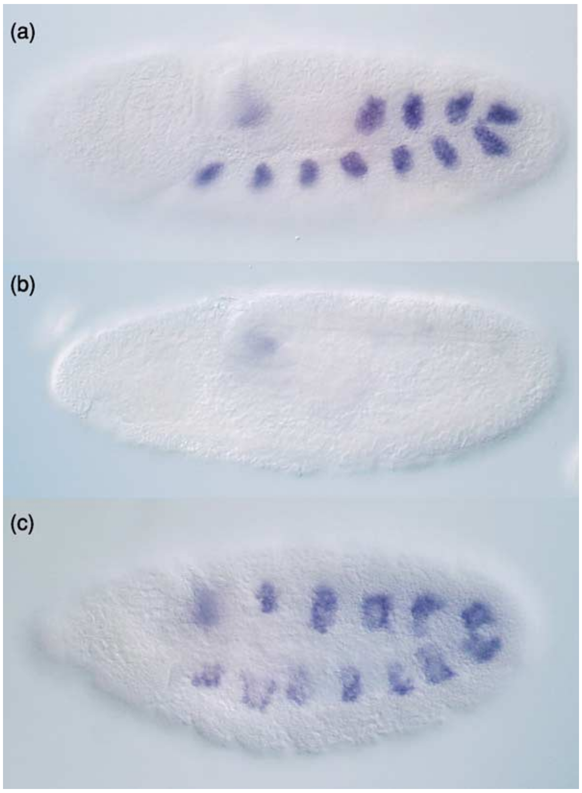

Figure 13 *Abd-B* suppresses visceral muscle formation. (a–c) Stage-11 embryos stained for Bap protein. (a) In wild-type embryos *bap* is expressed in 11 clusters in PS 2–12. (b) In *twi-GAL4*; *UAS-Abd-B* embryos, where Abd-B is expressed throughout the mesoderm, *bap*-expressing cells in the visceral muscle precursors are absent. (c) *Abd-B* mutant embryos have an ectopic *bap* cluster in PS 13. (Adapted with permission from Miller, J.M., **2002**. Analysis of the cell-specific expression of the *serpent* gene and its role as a cell-fate switch in *Drosophila melanogaster*. Ph.D. thesis, University of Nevada, Las Vegas.)

Based on misexpression experiments, *srp* is capable of repressing *bap* expression (Hayes *et al.*, 2001), and *Abd-B* may function in the dorsal mesoderm to specifically activate *srp,* which in turn inhibits cVM formation through the repression of *bap* expression. In *srp* mutants, ectopic *bap* clusters were not detected in PS 13, but this might be due to repression of cVM precursor specification by *Abd-B* (J.M. Miller and D.K. Hoshizaki, unpublished data). Because misexpression of *Abd-B* automatically leads to ectopic expression of *srp*, it cannot be determined from these experiments whether *Abd-B* can independently repress cVM formation. It is likely though that the normal absence of cVM precursors in PS 13 is due to the repression by both *Abd-B* and *srp*.

2.9.2.5. Summary

Over 25 years ago, Rizki and Rizki (1978) suggested that the larval fat body has a segmental origin. Recent studies have firmly established the segmental nature of the precursor fat cells and have identified different classes or groups of metamerically repeating cell clusters that contribute to the embryonic fat body (Abel *et al.*, 1993; Hoshizaki *et al.*, 1994; Riechmann *et al.*, 1998). The fat-cell precursors arise from unique anterior–posterior and dorsal–ventral positions within the mesoderm, which reflect the subdivisions of the mesoderm. A combination of positional information and input from different homeotic genes are involved in the establishment, maintenance, and differentiation of fat cells that populate the different regions of the fat body. The molecular mechanism underlying the commitment and specification of the different groups of mesodermal tissues relies upon *srp*, a GATA transcription factor gene involved in the specification and differentiation of fat cells (Rehorn *et al.*, 1996; Sam *et al.*, 1996; Hayes *et al.*, 2001) and, perhaps, represents a key component of the molecular machinery that determines cell-fate choices (Moore *et al.*, 1998; Riechmann *et al.*, 1998; Miller, 2002).

2.9.3. Origins of the Adult Fat Cells

The larval and adult cells are derived from two distinct groups of cells. During embryogenesis the

presumptive imaginal cells, which give rise to the adult epidermis, are segregated from the larval cells (reviews: Nöthiger, 1972; Bate and Arias, 1991). These imaginal cells reside in the larva either as discs of ectodermal cells surrounded by peripodial membrane or as clusters of cells known as histoblasts, which do not have a peripodial membrane. Imaginal cells are also integrated into their specific larval organ system, for example, the salivary gland and the gut. The imaginal cells are ectodermal in origin and the mechanism by which the mesodermal (adepithelial) cells become associated with the imaginal discs and eventually form the adult mesodermal derivatives in the head, legs, and thorax is not known. Only the adepithelial cells and the mesodermal histoblasts that give rise to muscle cells have been identified (Bate *et al*., 1991; Currie and Bate, 1991).

Transplantation studies of partial discs by Lawrence and Brower (1982) showed that the adepithelial cells associated with the presumptive notum of the dorsal mesothoracic (wing) disc are a source of adult muscle precursors. More recently, studies using *twi* as a cell marker for precursor adult muscle cells, have confirmed these observations and shown that *twi*-expressing adepithelial cells are associated with the leg, wing, haltere, and genital discs (Bate *et al*., 1991; Currie and Bate, 1991). In addition, *twi*-expressing histoblasts are located in each of the larval abdominal segments and are the precursor cells of the adult abdominal muscles (Currie and Bate, 1991).

The origin of the adult fat body is unclear. Robertson (1936) and Koch (1945) suggested that the abdominal fat body, oenocytes, and abdominal epidermis arise from histoblasts. Studies by Lawrence and Johnston (1986), however, have established that oenocytes and the abdominal epidermis share a common cell lineage, which is separate from the lineage that gives rise to the adult abdominal muscles. The lineage relationship of the fat-body cells with oenocytes, abdominal epidermis, and adult abdominal muscles was not determined owing to the lack of appropriate cell markers. It seems unlikely, though, that the adult abdominal fat cells would have a common cell lineage with the oenocytes and abdominal epidermis, because fat cells are derived from the mesoderm, while the oenocytes and abdominal epidermis are derived from the ectoderm.

Based on the analysis of two independent enhancer trap lines, X8-157a and 3-76a, the putative imaginal fat cells were identified as a subset of histoblast cells associated with the body wall of the larva, and as a subset of adepithelial cells associated with specific imaginal discs (Hoshizaki *et al*., 1995). The *lacZ* reporter gene associated with these two enhancer-trap lines exhibits activity in embryonic, larval, and adult fat cells and appears to mark all fat-cell lineages. In addition, *lacZ* activity is present in small clusters of cells (histoblasts) associated with the abdominal segments, and in adepithelial cells associated with the dorsal mesothoracic disc and the eye antennal disc (**Figure 14**). Furthermore, *lacZ* activity is present in the adepithelial cells located along the margin and does not overlap with the adepithelial cells of the adult muscle. Finally, *lacZ*-positive cells are also located in two clusters of adepithelial cells associated with the eye antennal disc.

These *lacZ*-positive adepithelial cells are associated with discs that give rise to structures containing fat cells. The dorsal mesothoracic disc gives rise to wing and thoracic structures, and eye-antennal discs give rise to head and antennal structures, all of which contain adult fat cells. In contrast, adult legs lack fat cells and, correspondingly, leg discs lack *lacZ*-positive adepithelial cells. Based on these correlations, it is likely that the *lacZ*-positive adepithelial cells and histoblasts in X8-157a and 3-76a lines represent the imaginal fat cells.

2.9.4. The Fat Body as an Endocrine Organ

The larval stage is characterized by rapid growth, which takes place mainly by an increase in cell size via endoreplication (Smith and Orr-Weaver, 1991; Royzman *et al*., 1997). The insect fat body has a central role in larval development by fueling this rapid growth through its participation in the intermediary metabolism. Results from a variety of studies suggest that the larval fat body also plays an active role in coordinating larval growth by monitoring the nutritional status of the animal and altering the feeding and other behavioral responses according to need (Section 2.9.4.3). Although most larval tissues undergo endoreplication (e.g., fat body, salivary glands, Malpighian tubules, trachea, muscle, and epidermis), the imaginal cells, which generate the adult-specific tissues, proliferate using a mitotic cell cycle. From studies in *D. melanogaster*, it is known that these mitotic tissues include imaginal discs, larval neuroblasts, the germ cells, and the abdominal histoblast nest. Each of these groups of cells exhibits a specific temporal proliferation pattern and, in most cases, proliferation is initiated after the first-instar larvae begin to feed (Nöthiger, 1972). The control of imaginal cell proliferation also appears to be dependent upon the fat body

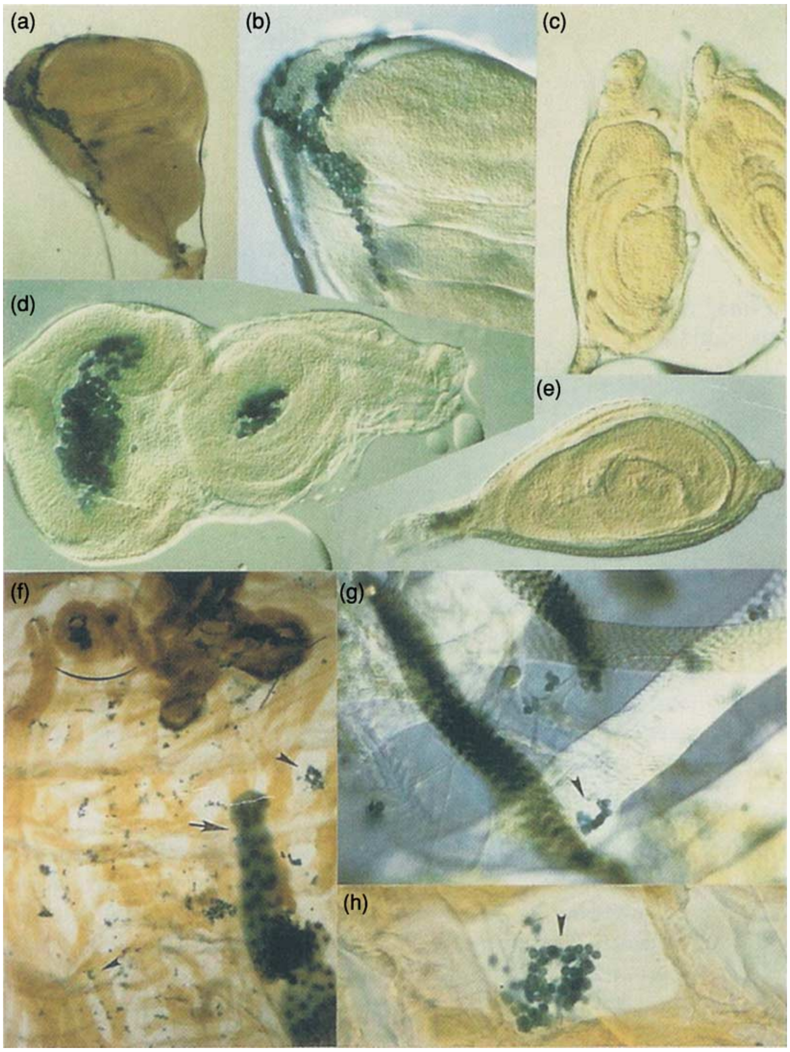

Figure 14 Identification of imaginal fat-body cells. *lacZ* activity in adepithelial cells of various imaginal discs and the fat-body cells in the enhancer-trap line X8-157a. *lacZ*-positive cells (dark staining) are detected in (a) the dorsal mesothoracic and (d) eye-antennal disc; (b) is a higher magnification of (a). *lacZ*-positive cells are not detected in the paired prothoraic discs (c) nor in the mesothoracic leg disc; (e). (f) Body wall and fat body (arrow) from dissected third-instar larva. The *lacZ*-positive adepithelial cells are associated with the body wall (arrowheads) and with specific imaginal disc, for example, eye-antennal disc (arc). (g, h) Higher magnifications of adepithelial cells associated with the body wall (arrowheads) in (f). (Reproduced with permission from Hoshizaki, D.K., Lunz, R., Ghosh, M., Johnson, W., **1995**. Identification of fat-cell enhancer activity in *Drosophila melanogaster* using P-element enhancer traps. *Genome 38*, 497–506.)

through the production of fat body mitogenic growth factors (Sections 2.9.4.1 and 2.9.4.2).

2.9.4.1. Fat Body, Cell Growth, and Differentiation

Since the initial efforts to culture insect cells and tissues, the addition of fat body or medium preconditioned with fat body was found to be an important requirement for *in vitro* cell proliferation and differentiation. The early work of Davis and Shearn (1977), for example, has shown that *in vitro* cultures of *D. melanogaster* imaginal discs require fat-body conditioned medium, insulin, and a juvenile hormone (JH) analog for their maintenance. These supplements allow for optimal growth and normal cell division. Furthermore, imaginal discs cultured with these supplements can maintain their capacity to differentiate into normal patterns of adult cuticular structures. *In vitro* cuticle deposition in cultured lepidopteran imaginal discs is also dependent upon fat-body conditioned media (and 20-hydroxyecdysone; 20E), but is inhibited by JH (Oberlander and Tomblin, 1972; Dutkowski and Oberlander, 1974; Oberlander, 1976b). The *in vitro*

differentiation of isolated stem cells from the midgut of *Manduca sexta* larvae is also dependent upon the presence of fat-body conditioned media (Sadrud-Din *et al*., 1994, 1996). In the early 1990s Loeb and Hakim (1991) reported that 20E-stimulated fat body could induce the development of the genital imaginal disc of *Heliothis virescens in vitro*. Nine fractions from 20E-treated fat body were identified that could promote growth and development of the genital tract (Loeb, 1994). More recently, it was shown that co-culture of fat bodies from feeding larvae with quiescent central nervous systems from starved larvae can specifically induce neuroblast proliferation (Britton and Edgar, 1998). Based on a variety of tissue and cell culture studies, it is clear that the fat body is a source of secreted systemic growth factors.

2.9.4.2. Fat Body and the Production of Growth Factors

Genetic and biochemical studies have further established the role of the fat body as an endocrine organ and provided evidence that the fat body is a critical player in coordinating cellular growth with the nutritional status of the animal. The gene *minidiscs* (*mnd*) is expressed in the fat body and is responsible for a secreted factor necessary for imaginal disc proliferation (Martin *et al*., 2000). Mutations in *minidiscs* result in smaller imaginal discs and brain lobes, the fat body appears to be depleted of lipids, and these mutant animals die late in larval development (Shearn *et al*., 1971; Martin *et al*., 2000). Based on sequence analysis, *minidiscs* encodes an integral membrane protein with 12 putative membrane-spanning domains that has sequence similarities to amino acid transporter subunits from other eukaryotes (Martin *et al*., 2000). *In situ* hybridization studies have shown that *minidiscs* is ubiquitously expressed initially in the early embryo and, later, is expressed primarily in the embryonic fat body. In the larva, *minidiscs* is predominately expressed in the fat body, although weak expression is also detected in the imaginal disc and the optic lobes of the brain (Martin *et al*., 2000). Consistent with the biochemical and sequence data, transplanted *minidiscs* mutant discs grow in nonmutant hosts, suggesting that *minidiscs* dependent factors produced in the fat body are released into the hemolymph and are necessary for imaginal disc proliferation (Martin *et al*., 2000). The mechanism of *minidiscs* action on imaginal proliferation has yet to be determined, but it may coordinate imaginal disc proliferation and maturation in response to amino acid uptake and subsequent production of an imaginal disc specific growth factor(s).

Studies by Bryant and co-workers (Kawamura *et al*., 1999; Zurovec *et al*., 2002) have identified two classes of growth factors produced by the fat body. The family of imaginal disc growth factors (IDGFs) was isolated by systematically identifying extrinsic growth factors from conditioned medium (Kawamura *et al*., 1999), while the adenosine deaminase-related growth factors (ADGFs) were identified by sequence homology to insect-derived growth factors from *Sarcophaga* cells (Zurovec *et al*., 2002). The ADGFs stimulate imaginal disc proliferation and one of them, ADGF-D, is expressed primarily in the fat body and brain.

The IDGF family is expressed most strongly in the embryonic yolk cells and in the fat body of the embryo and larva, respectively. This family of factors may correspond to the mitogenic factors responsible for growth in fat-body conditioned media (Davis and Shearn, 1977; Kawamura *et al*., 1999). The IDGF proteins are structurally related to chitinases, but they have an amino acid substitution known to abrogate catalytic activity. Thus, it seems likely that these proteins evolved from chitinases that acquired a new growth-promoting function (Kawamura *et al*., 1999). Recombinant forms of IDGF1 and IDGF2 promote cell proliferation in the imaginal disc cell line C1.8 and promote cell growth and formation of pseudopodia in the presence of insulin (Kawamura *et al*., 1999). The cooperation between IDGFs and insulin in stimulating imaginal disc cell growth suggests that the IDGFs might function as cofactors to insulin and insulin-like peptides (Stocker and Hafen, 2000; Ikeya *et al*., 2002), which promote growth in *Drosophila* primary cultures (Echalier, 1997) and are necessary for proliferation of some imaginal disc cells (Cullen and Milner, 1991).

2.9.4.3. Fat Body and the Control of Feeding Behavior

It has been long established that the fat body has a central role in intermediary metabolism (Keeley, 1985; see also **Chapters 4.6** and **4.8**); however, evidence is accumulating that the fat body also plays an active role in establishing energy homeostasis through altering feeding and other behavioral responses. Based on a genetic screen to isolate mutant larvae defective in feeding, Zinke *et al*. (1999) identified *pumpless* (*ppl*), a behavioral mutant involved in suppressing food intake in response to amino acids. During the first larval stage, the *ppl* mutant larvae first accumulate food in the pharynx, and then move out of the food and begin to wander. These animals have a drastic reduction in growth and eventually die as small larvae (Zinke *et al*., 1999). Although these animals appear to have a

blockage in the pharynx, the entire larval feeding apparatus, the pharynx, esophagus, and proventriculus, appear normal (Hartenstein *et al*., 1994; Zinke *et al*., 1999). The wandering *ppl* mutants also do not appear to be starving, because starvation markers such as Lipase3 and hosphoenolpyruvate Carboxykinase (Pepck) are not elevated (Zinke *et al*., 1999). The *ppl* gene is expressed specifically in the fat body and codes for a protein, which has high homology to the vertebrate protein H subunit of the glycine cleavage system. This vertebrate enzyme complex is involved in the catabolism of glycine into ammonia, carbon dioxide, and other one-carbon molecules.

The *ppl* gene is likely to also be involved in amino acid metabolism through the catabolism of glycine and the generation of one-carbon molecules. Surprisingly, the addition of high levels of lysine, but not glycine, in the culture medium of wild-type animals phenocopies the characteristic accumulation of food in the pharynx and the growth reduction (Zinke *et al*., 1999). The mechanism by which the fat body and *ppl* may monitor changes in the quality or composition of the food source is not known. Shortly before pupariation, an ecdysone (20E) pulse signals a change in behavior and the larvae go through the transition from a feeding to a wandering nonfeeding larval stage (Riddiford, 1993). It is possible that *ppl* coordinates the nutritional status the animal (or the fat body) with this ecdysone pulse. The premature cessation of food intake and precocious initiation of wandering that occurs in the *ppl* mutant might reflect a premature activation of the wandering program.

2.9.5. Fat-Body Dissociation and Remodeling

During the last larval instar, at the onset of metamorphosis, the fat body undergoes extensive structural reorganization as its function changes and the animal undergoes the transition from larval to adult life. The fat body switches from the production and secretion of storage proteins, which serve as a source of polypeptides and amino acids for the re-architecture of the animal into the adult form (Haunerland, 1996; review: Burmester and Scheller, 1999), to the re-adsorption of these proteins from the hemolymph. The storage proteins are subsequently sequestered into large proteinaceous storage granules. During metamorphosis, these proteins are used as a source of polypeptides and amino acids for the re-architecture of the animal into its adult form (Haunerland, 1996; review in Burmester and Scheller, 1999). Early in metamorphosis the fat body undergoes a striking transformation from an organized tissue to a loose association of individual fat cells (Dean *et al*., 1985; Keeley, 1985). In the majority of insects, fat-body cells survive metamorphosis and undergo cellular reconstruction and transformation into the adult fat cells (Larsen, 1976). However, in some Hymenoptera and in the higher Diptera, the dissociated larval fat-body undergoes cytolysis in the adult and is replaced by an adult fat body, which arises from imaginal fat cells (Dean *et al*., 1985; Keeley, 1985; Hoshizaki *et al*., 1995).

Extensive studies describing fat body structure based on electron micrographs have been published for *Calpodes ethlius*, *Rhodnius prolixus*, *Periplaneta americana*, *Locusta migratoria*, and *Apis mellifera* (Locke, 1998). The last general review of fat body reorganization, however, was published over a decade ago (Rizki, 1978; Dean *et al*., 1985; Keeley, 1985). The most noted advances in our understanding of the events involved in fat-body dissociation during metamorphosis have taken place in *Sarcophaga peregrina* and *D. melanogaster.* In *S. peregrina*, the hemocytes appear to control the breakdown of the fat-body tissue into individual fat cells, while in *D. melanogaster* cellular signaling pathways have been identified that could establish fat body competence to undergo dissociation. The recent advances and the new experimental tools available in *D. melanogaster* should allow us to obtain further insights into fat-body dissociation and remodeling and are discussed below.

2.9.5.1. Fat-Body Reorganization: Morphological Changes

During metamorphosis the fat body undergoes a striking transformation that leads to its dissociation into independent cells. Fat body cells, like all insect cells with the exception of the hemocytes, are encased within a basal lamina (Ashurst, 1982). The fat body is made up of a single cell layer of cells that form sheets of tissue. The basal lamina of both the apical and basal surfaces of the fat body is exposed to the hemolymph while the lateral regions are associated with a basal lamina that is held to the plasma membrane by hemidesmosomes between adjacent fat cells (Dean *et al*., 1985). Below the basal lamina, the plasma membrane of the fat cells forms a reticular system from subsurface inward folding of the cell membranes that surround each of the fat cells (**Figure 15**) (Butterworth and Forrest, 1984; Locke, 2003). Studies on the fat body in *C. ethlius* and *R. prolixus* highlight the nature of the basal lamina and the plasma membrane reticular system that surround the fat body (review: Locke, 2003). Both the basal lamina and the entrance to the reticular system are selectively permeable and func-

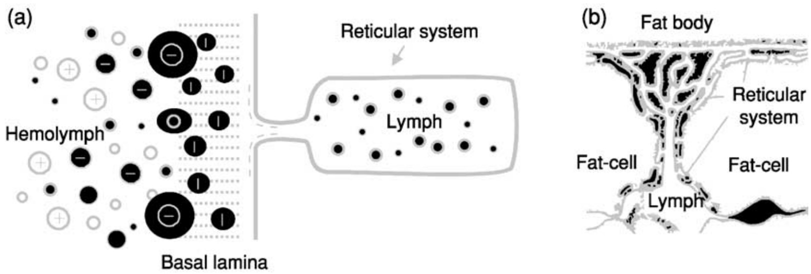

Figure 15 The reticular membrane system of the fat body. (a) The plasma membrane reticular system and intercellular lymph spaces are separated from the hemolymph by negatively charged barriers tending to exclude large positively charged particles. Both the basal lamina and reticular system entrances are negatively charged sieves (Brac, 1983). (b) Many insect cells interface with their environment through a compartment of their own creation. Fat body cells elaborate the lymph spaces between them by the extension of surface processes. They also fold their surface membrane inward to create reticular systems. (With permission, from the *Annual Review of Entomology*, Volume 48; © 2003 by Annual Reviews www.annualreviews.org.)

tion as negatively charged sieves that restrict the passage of charged molecules larger than 15 nm in diameter (Brac, 1983; Locke and Huie, 1983; Reddy and Locke, 1990). This restricted flow is likely to result in a lymph space between the basal lamina and plasma membrane that lacks positively charged and larger molecules (**Figure 15a**) (review: Locke, 2003). Whether components of the lymph and the plasma membrane reticular system play a role in basal lamina degradation is not known.

In Lepidoptera, fat-body cells lose their adhesion to each other and to the tracheoles during metamorphosis (Larsen, 1976). The mechanism of fat body breakdown is not known; however, because hemocytes associate with the fat body during metamorphosis, it is likely that the hemocytes might play a role in the degradation of the fat-body basement membrane and the release of fat cells. In *C. ethlius* the individual fat cells re-organize and become associated in nodular clumps surrounding the tracheoles. The dissociated fat cells undergo a type of programmed remodeling, where the mitochondria, microbodies, and rough endoplasmic reticulum become sequestered in organelle-specific autophagic vacuoles and are destroyed by hydrolytic enzymes (Locke and Collins, 1968; Locke, 1971, 1998). The cells, however, persist and new populations of the organelles are regenerated shortly after the eclosion of the adult (Larsen, 1976; Locke, 1998).

In *D. melanogaster* most of the larval tissues undergo autophagy and compete histolysis during metamorphosis (review: Thummel, 2001). The fat body, however, is transformed from an intact tissue to individual fat cells that are dispersed throughout the pupa. The larval fat cells persist through metamorphosis and are present in the newly eclosed adult; there are no reports of fat cells undergoing cellular remodeling (Rizki and Rizki, 1970; Rizki, 1978). The "larval" fat cells in young adults are present as single and small clumps of cells that float freely in the adult body cavity (Hoshizaki *et al*., 1995). Approximately 1000 "larval" fat cells are found in the abdomens of newly eclosed male adults (Butterworth, 1972). This is less than the 1700 fat cells estimated to be present in the adult male abdomen and the estimated number of fat body cells in male larvae (2161 ± 54 cells) (Rizki, 1969; Butterworth, 1972). Based on these observations, it is possible that a portion of fat-body cells undergo cell death during metamorphosis. To date, however, there is no direct experimental evidence for fat-cell death during metamorphosis. Approximately 90% of the "larval" fat cells present in the adult disappear within the first two days of adult life, while the remaining cells disappear by day 4. This process has been referred to as histolysis, but as suggested by Richard *et al.* (1993), it is best described as cytolysis because the fat body has already dissociated into individual cells. The "larval" fat cells are replaced by adult fat cells that are thought to arise from the adepithelial cells of the dorsal thoracic and eye-antennal discs and by the histoblasts that are associated with the body wall of the larva (Hoshizaki *et al*., 1995).

Although the mechanism of fat-cell elimination in the adult is unclear, it is thought to involve a form of programmed cell death. Early studies suggested that JH triggers the elimination of the "larval" fat cells based on the observation that the removal of the *corpus allatum* from young *Sarcophaga* adults prevented the loss of these cells (Day, 1943). The isolation of *apterous*^{4} (*ap*^{4}), a nonvitellogenic, JH-deficient mutant of *D. melanogaster* in which the "larval" fat cells in the adult do not undergo complete cytolysis, lent further support to this idea (Butterworth and King, 1965; Butterworth, 1972). In transplantation experiments, the behavior of the *ap*^{4} fat body is not cell autonomous (Butterworth

and Bodenstein, 1967; Butterworth, 1972). Head-abdomen ligation experiments mimic the ap^4 fat body mutant phenotype, and the application of the JH mimic methoprene (ZR515) to isolated abdomens and to mutant animals restores normal cytolysis and vitellogenesis (Postlethwait and Jones, 1978). These observations suggest a causal role of JH in the cytolysis of the "larval" fat cells in the adult. However, additional experiments showed that although the application of methoprene could indeed elicit the initiation of vitellogenesis, it could *not* restore histolysis in the ap^4 mutants (Richard *et al*., 1993). Furthermore, the absence of cytolysis is unique to the ap^4 mutant; other *ap* mutants exhibit cytolysis even though they also have low levels of JH (Richard *et al*., 1993). Thus, reduced levels of JH may not be causative for the loss of cytolysis of the "larval" fat cells in ap^4 mutant adult.

The deduced amino acid sequence of the Apterous (Ap) protein predicts a homeo domain and a cysteine/histidine-rich domain that make it a member of the LIM (Lin-11/Isl-1/Mec-3) homeobox family of regulatory proteins (Cohen *et al*., 1992). The *ap* gene has the capability of eliciting a number of independent biological process (review: Richard *et al*., 1993), which are not dependent upon normal JH production; one of them may be the induction of "larval" fat-cell cytolysis in the adult.

The early work of Rizki (Rizki and Rizki, 1970; Rizki, 1978) described the gross changes in fat-body dissociation, cell reorganization during metamorphosis, and the location of the dissociated fat cells within the newly emerged adults. The position of the larval fat cells within the pupa is retained in the adults and can be followed using the mutant combination *tumor (2)*^{w} (*tu*^{w}); *red cells* (*rc*) (Rizki, 1978; see also below).

Current advances in cell biology techniques have provided new tools that allow more detailed descriptions of tissue changes during metamorphosis (Ward *et al*., 2003). Thus, the development of green fluorescent protein (GFP) cell markers expressed in specific tissues has greatly improved the ability to visualize cells *in vivo*. Studies using differential interference contrast (DIC) and fluorescent microscopy in combination with GFP fat-cell markers make it possible to describe fat-body dissociation in live animals (**Figure 16**).

Several descriptions of the gross changes that occur during metamorphosis in *D. melanogaster* have been published earlier, although these accounts do not focus on the fat body (Robertson, 1936; Bodenstein, 1950; Bainbridge and Bownes, 1981; Ashburner, 1989). The early stages of metamorphosis with regard to the changes in the fat body can be summarized as follows (**Figure 16**). At 25 °C, approximately 10 h prior to pupariation, the larva leaves the food and begins the "wandering stage." This behavior is triggered by a small rise in the ecdysone (20E) titer, which begins 24 h after ecdysis to the third instar (Schwartz *et al*., 1984). During this stage, the larval fat body is recognized as sheets

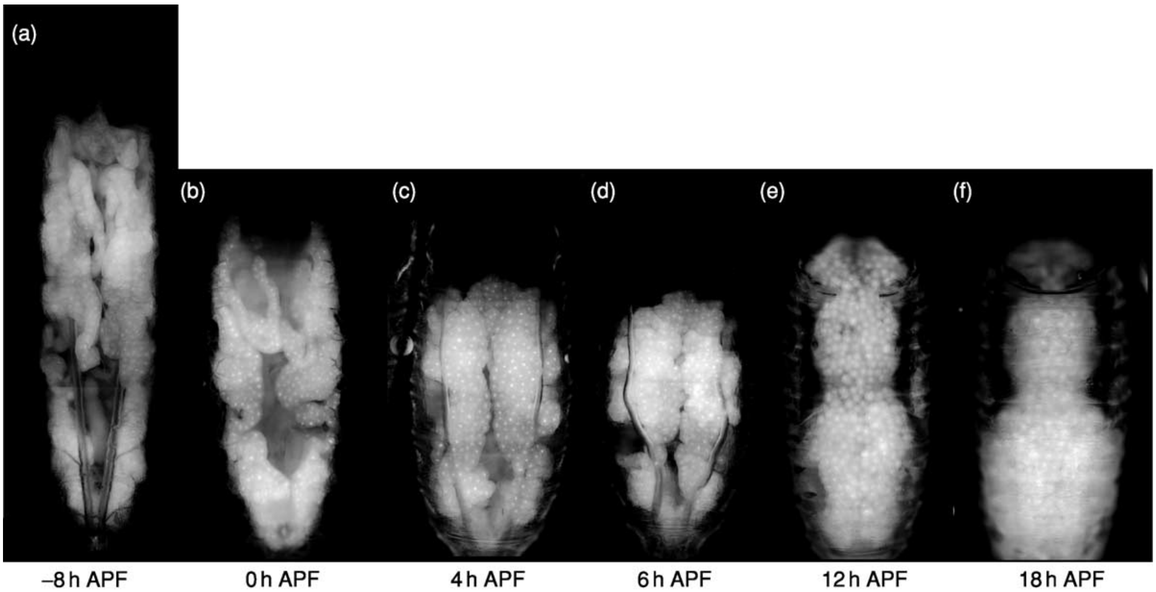

Figure 16 Third-larval instar and early pupal stages of *D. melanogaster*. Fluorescent images of fat-body cells from live animals expressing green fluorescent protein. (a) Late third-instar larva; (b) white prepupa; (c) pre-apolysis larva; (d) early prepupa; (e) early pupa; and (f) late pupa. (AFP is hours after puparium formation at 25 °C.)

of white, translucent cells that float in the hemolymph between the body wall and the midgut (Figure 16a). Pupariation is triggered by a large rise in the 20E titer in the hemolymph (Richard *et al.*, 1993). At this time, the larva shortens and becomes immobile, forming what is generally referred to as a white prepupa (wpp), a stage that lasts approximately 10 min and represents a convenient developmental marker from which to stage animals (Bodenstein, 1950). At this stage, the animal is still a larva because neither apolysis nor ecdysis have occurred (Ashburner, 1989). The fat body can be visualized through the cuticle using light or fluorescent microscopy; the gross morphology of the fat body is unchanged, and the fat body fills most of the peripheral space between the body wall and the gut (Figure 16b).

Hardening and tanning of the larval cuticle leading to the formation of the puparium cuticle occurs over the next 3.5 h. Approximately 4–6 h after puparium formation (APF), apolysis occurs and the epidermis is separated from the puparium cuticle, which now represents the outermost pupal cuticle. Between pupariation and apolysis, the animal is still a larva but has often incorrectly been referred to as a prepupa (Ashburner, 1989). During this time the fat body retracts from the anterior region of the animal (Figure 16c). Consistent with the observation of Rizki (1978), at 6 h APF, the fat-body cells from the head region are completely displaced toward the abdominal region, while the fat body still appears as an intact tissue (Figure 16d). Pupation occurs at 12 h APF and is triggered by a small rise in 20E (Handler, 1982; Sliter and Gilbert, 1992). Post-apolysis, the fat body is restricted to the abdominal region and begins to acquire a loose appearance, with the anterior cells appearing more spherical in shape, suggestive of a loss in cell–cell adhesion (Figure 16e). Pupation occurs at 12 h APF and is triggered by a small rise in 20E (Handler, 1992; Sliter and Gilbert, 1992). The muscular contractions that drive head eversion also release individual fat cells from the bulk of the fat-body cells. The anterior-most fat cells are released first and are distributed into the head region. Upon completion of head eversion, the entire fat body dissociates into individual spherical fat cells. At 18 h post pupariation the fat cells are freely packed in the open interior space of the pupa (Figure 16f).

2.9.5.2. Fat-Body Reorganization: Biochemical and Cellular Interactions

Little is known about the controlled breakdown of the fat-body basement membrane and the subsequent release of fat cells. Reports by Rizki (Rizki and Rizki, 1974a, 1974b, 1979) describe the breakdown of the basement membrane in the *D. melanogaster* mutant strain tu^{w} and the associated transformation of the spherical hemocytes to the flattened lamellocytes, which is normally seen during pupal development. Based on scanning electron micrographs, the tu^{w} fat body shows signs of dissociation in the caudal fat cells prior to the hemocyte changes. The caudal fat body of tu^{w} larvae grown at 25 °C exhibits abnormal loss of basement membrane 72 h after hatching. During the interval from 72 to 86 h, plasmatocytes and podocytes aggregate at the exposed cell surface and flatten to form layers of lamellocytes. By 93 h after hatching, the caudal fat body is encapsulated into a compact melanized mass (Rizki and Rizki, 1974a). These observations suggest that the breakdown of the basement membrane is an underlying factor in marking the site that the hemocytes will encapsulate. The particulate material that accumulates on and around the caudal fat cells may trigger the response of the hemocytes. If the metamorphosing fat body normally provides a signal that triggers the fat body-hemocytes association, then the observed premature appearance of lamellocytes in tu^{w} larvae might be due to caudal fat body taking on a "pupal" fat body status (Rizki and Rizki, 1974a). These observations suggest that in *D. melanogaster* the fat body plays a role in signaling its own dissociation.

In *S. peregrina* the dissociation of the fat body is mediated by hemocytes that associate with and degrade the basement membrane of the fat body. Key to understanding the dissociation process in *S. peregrina* was the establishment of an *in vitro* system that mimiced the dissociation of the fat body during metamorphosis (Kurata *et al.*, 1989). The prepupal hemocytes (4–6 h APF at 27 °C), but not the larval hemocytes, were shown to be capable of dissociating both larval and pupal fat body *in vitro*, and causing the release of individual fat cells (Kurata *et al.*, 1989). These results suggest that, after pupariation, the hemocytes acquire the ability to dissociate the fat body and that, at least *in vitro*, both larval and pupal fat body are susceptible to dissociation.

The dissociation of the fat body is mediated by the release of a 29 kDa Chymotrypsin-like protease from the hemocytes (Kurata *et al.*, 1990). The 29 kDa protein has been cloned and, based on sequence comparisons, was shown to correspond to Cathepsin B, a cysteine protease involved in intracellular degradation and turnover of proteins (Takahashi *et al.*, 1993). Cathepsin B is synthesized as a 344 amino acid pro-protein with a 20 amino acid putative signal sequence and a 68 amino acid pro region, both of which are cleaved to produce an

256 amino acid active enzyme (Takahashi *et al.*, 1993). The substrate specificity of *S. peregrina* Cathepsin B (S-Cathepsin B) is unique: it recognizes the peptidyl substrates Suc-Leu-Leu-Val-Tyr-MCA and Z-Phe-Arg-MCA (Suc, succinyl; MCA, methylcoumaryl-7-amide; Z carbobenzoxy), two substrates for Chymotrypsin and Cathepsin B and L (Kurata *et al.*, 1992b), but not the Chymotrypsin and Cathepsin B substrates Suc-Ala-Ala-Pro-Phe-MCA and Z-Arg-Arg-MCA, respectively (Kurata *et al.*, 1992b).

In *S. peregrina* the pupal, but not the larval, hemocytes are active in fat-body dissociation, thus it is likely that fundamental changes occur in the hemocytes during pupariation to facilitate hemocyte-fat body association and/or to activate Cathepsin B. Based on indirect immunofluorescence microscopy, Cathepsin B protein is located in heterogeneous granules in a subset of pupal hemocytes (Kurata *et al.*, 1992a). Early reports also suggest that the degranulation and subsequent release of active Cathepsin B from the hemocytes is mediated through hemocyte-fat body interactions (Kobayashi *et al.*, 1991; Kurata *et al.*, 1991).

Recognition molecule(s) carried on pupal hemocytes are proposed to stimulate hemocyte secretion of Cathepsin B upon interaction with the fat body basement membrane. A 200 kDa pupal hemocyte-specific membrane protein was reported as a candidate recognition molecule (Kobayashi *et al.*, 1991; Kurata *et al.*, 1991), but a recent study showed that this protein is myosin heavy chain derived from muscle fragments and not from pupal hemocytes (Hori *et al.*, 1997; Natori *et al.*, 1999).

2.9.5.3. Fat-Body Reorganization: Role of Ecdysone and TGF-β Signaling

The controlled breakdown of the fat body into its individual cells is a normal event during metamorphosis and is likely to be also regulated by the 20E pulse associated with pupariation formation. *In vitro*, the dissociation of the fat body occurs in a 20E dose-dependent manner (Oberlander, 1976a). This observation suggests that fat-body dissociation is cell autonomous and does not require pupal hemocytes. The first *in vivo* experimental evidence demonstrating a role for 20E in fat-body dissociation came from studies designed to distinguish the function of different ecdysone receptor (EcR) isoforms (Cherbas *et al.*, 2003). These authors developed dominant-negative mutants of EcR (EcR-DN), EcR-F645A and EcR-W600A which block ecdysone signaling. Regulated expression of *EcR-DN* was achieved through the use of the GAL4/UAS system that allows controlled expression of genes (Brand and Perrimon, 1993). Using this system, ecdysone signaling was blocked specifically in the fat body through the use of the *Larval serum protein 2* (*Lsp2*) promoter. The *Lsp2* gene is expressed specifically in the fat body early after ecdysis to the third instar, and *Lsp2* transcripts reach maximum steady-state levels at mid-third instar (Andres *et al.*, 1993). Expression of *Lsp2* is also detected in the prepupa, albeit at lower levels (Andres *et al.*, 1993). The disruption of 20E signaling in the fat body by expression of the dominant negative *EcR* prevented the dissociation of the fat body (Cherbas *et al.*, 2003). These data confirm that 20E signaling is involved in fat body dissociation during metamorphosis.

During metamorphosis only the fat body undergoes programmed tissue dissociation, while other tissues are subjected to 20E-dependent autophagy (review: Thummel, 2001). It is likely that other signaling pathways are integrated with 20E signaling to initiate the breakdown of the fat body. Genetic analysis has revealed that the fat body is extremely sensitive to the disruption of transforming growth factor-β (TGF-β) signaling pathway, which results in premature dissociation of the larval fat body.

The details of TGF-β signaling in *D. melanogaster* are well understood; its components (receptors and Smads) that transduce the TGF-β signal have been identified and many of their biochemical interactions have been characterized (**Figure 17**) (review: Massague *et al.*, 2000; Massague and Chen, 2000; Massague and Wotton, 2000). The TGF-β secretory polypeptide family controls multiple developmental processes in *D. melanogaster* through its receptors and a network of Smad transcription factors, which mediate changes in gene transcription.

Loss of TGF-β/Smad signaling, as detailed below, results in the premature dissociation of the larval fat body and loss of fat-body cells. Because TGF-β/Smad signaling mediates cellular responses through the activation or repression of target genes, it is possible that some target genes directly or indirectly regulate adhesion molecules, proteases, or regulatory components involved in the maintenance or degradation of the fat body basal lamina, or participate in the fat body-induced response of hemocytes.

In *Drosophila*, there are four TGF-β related factors, Decapentaplegic (Dpp), Glass-bottom-boat (Gbb), Screw, and Activin. The TGF-β ligands function as dimers and signal through transmembrane protein serine/threonine kinases known as type I and II receptors, which also function as homodimers. The TGF-β ligands serve to bring the two receptors together, such that the type II receptor can phosphorylate the type I receptor at its GS domain, thereby activating the type I receptor kinase. The

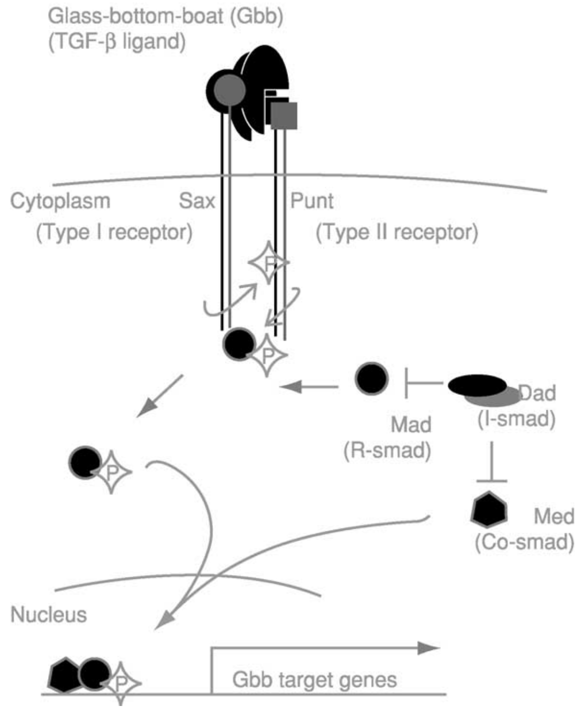

Figure 17 Schematic representation of TGF-β signaling network highlighting *Drosophila* Glass-bottom-boat/Smad signaling network. The *D. melanogaster* ligand Gbb signals through the type II receptor Punt and the type I receptor Sax. Ligand binding stimulates formation of an active receptor complex that phosphorylates Mad, which, in turn, oligomerizes with Medea (Med). The Mad/Med complex functions as a transcription factor to activate target genes.

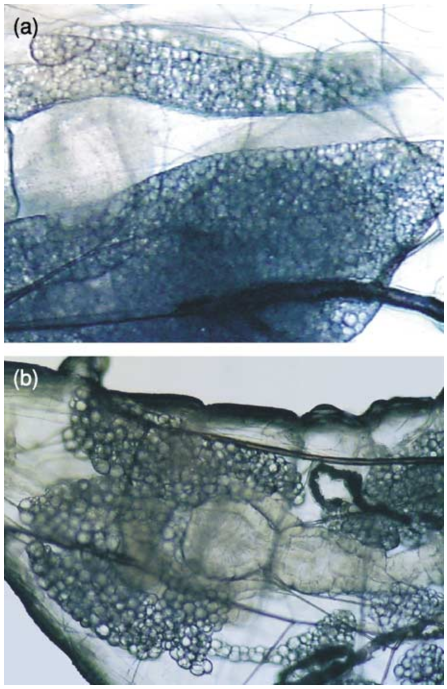

Figure 18 Loss of *sax* leads to a morphological change in the larval fat body. (a) Wild-type fat body. The fat body remains intact until metamorphosis when the fat body dissociates into individual cells. (b) Fat body from a *sax* mutant grown at 18 °C. The fat body is loosely organized; later the fat body dissociates into individual cells. The *sax* mutants do not metamorphose and the individual fat body cells are thought to eventually undergo apoptosis.

TGF-β signal is transduced from the receptor–ligand complex to the cytoplasm by the phosphorylation of Smad proteins (Mothers-against-decapentaplegic (Mad) and Medea (Med)) which, in turn, function as transcription factors (Figure 17) (Raftery and Sutherland, 1999).

2.9.5.3.1. Mutations in TGF-β signaling The TGF-β ligand, Glass-bottom-boat (Gbb) (also known as 60A) interacts synergistically with Dpp in several developmental process including wing disc patterning, embryonic mid-gut morphogenesis, and embryonic ectoderm patterning (Khalsa *et al.*, 1998; Wharton *et al.*, 1999; see also **Chapters 1.8** and **1.9**). A striking feature of the *gbb* mutant is its defect in both the quantity and quality of the fat body resulting in a transparent mutant larva, hence the name of the gene. This fat body phenotype is not detected in *dpp* mutants, and thus the Gbb signaling network that controls fat body morphology is independent of Dpp signaling (Chen *et al.*, 1998; Khalsa *et al.*, 1998; Wharton *et al.*, 1999). A detailed developmental time course describing fat body changes and loss of fat body cells in *gbb* mutants has not been reported yet.

The *Drosophila* TGF-β ligands (Gbb, Screw, Dpp, and dActivin) signal through the same type II receptor, Punt, but also use unique type I receptors. Based on genetic interaction studies, the type I receptor Saxophone (Sax) mediates Gbb signaling. In genotypes containing a single copy of a *sax* null allele, the viability of *gbb* homozygous mutants is compromised (Khalsa *et al.*, 1998). Although mutations in *sax* result in embryonic lethality, the sax^4 allele is temperature sensitive (D.K. Hoshizaki, unpublished data). Mutant sax^4 larvae grown at 18 °C develop through late-third instar, but fail to pupariate. During the third instar the fat body becomes transparent and the fat cells appear loosely associated with each other and begin to round up (Figure 18). Consistent with the *sax* participation in Gbb-signaling, the *sax* and *gbb* mutants have similar fat body defects.

The first identified substrates of the type I receptor kinase were the *Drosophila mothers-against-decapentaplegic* (*mad*) gene and the *C. elegans Sma* gene. These proteins established the Smad family of conserved signal transducers and transcription

factors (review: Raftery and Sutherland, 1999; Moustakas *et al*., 2001). In *Drosophila*, the Smad family is made up of two receptor Smads (R-Smads, Mad, and dSmad2), a single common Smad, (Co-Smad, Medea), and a single inhibitory Smad (I-Smad, Daughters-against-decapentaplegic (Dad)) (**Figure 17**) (review: Raftery and Sutherland, 1999). Both *medea* and *mad* were isolated as dominant enhancers of *dpp* mutant phenotypes (Raftery *et al*., 1995; Sekelsky *et al*., 1995). Homozygous *mad* and *medea* mutants have reduced imaginal discs, and exhibit pupal lethality and defects in midgut morphogenesis. These mutant phenotypes are consistent with Mad/Medea's role in transducing the Dpp signal. *mad* and *medea* mutants also have fat body defects that are not seen in *dpp* mutants but are similar to the *sax* fat body mutant phenotype (Raftery *et al*., 1995; Sekelsky *et al*., 1995; D.K. Hoshizaki, unpublished data). Based on expression studies using a *mad* enhancer trap, *mad* was demonstrated to be expressed in the fat body (D.K. Hoshizaki, unpublished data). This observation suggests that Gbb-signaling through Sax, Mad, and Medea takes place within the fat body cells and that loss of signaling by these factors results in the disruption of fat body structure.

2.9.5.4. Speculation

Taken together, the studies from *Sarcophaga* and *Drosophila* provide the genetic, cellular, and biochemical information that is necessary in order to build a working model for the control of tissue dissociation. In this model, ecdysone signaling induced by the ecdysone pulse that also triggers pupariation has a role in establishing fat body competence for dissociation. In the larva, maintenance of the fat body integrity is controlled by Gbb/Smad signaling which is down-regulated by ecdysone at the onset of metamorphosis. Because TGF-β signaling is known to be integrated with other signaling networks (Wotton *et al*., 1999; Attisano and Wrana, 2002; Lutz and Knaus, 2002), cross-talk between ecdysone and TGF-β signaling *within* the fat body may result in fat body acquisition of competence for dissociation. Based on data from *Drosophila*, the events that trigger dissociation are intrinsic to the fat body. However, in *S. peregrina* fat body dissociation is hemocyte-mediated and dependent on fat body-hemocyte interactions. It is likely that fat body dissociation involves both fat body intrinsic events and the interplay with the hemocytes that provide Cathepsin B. As part of the working model, an ecdysone pulse also triggers events in the hemocytes that may also be related to translation of Cathepsin B. Alternatively, interactions between hemocyte recognition proteins and specific binding sites on the fat body may activate Cathepsin B through the cleavage of the pro-enzyme and the local release of Cathepsin B from storage granules. The *D. melanogaster Cathepsin B* gene has been cloned and identified as a recessive lethal mutation (Bourbon *et al*., 2002; Flybase, 2003). Thus, it should be possible to examine the cellular regulation of Cathepsin B *in vivo* and test the specific role of the fat body and the hemocytes in the fat body dissociation events using the advanced cell biology tools and genetic approaches that are available in *D. melanogaster.*

Acknowledgments

I am grateful to the undergraduate students Nichole Bond, Jenifer Utz, and Jeffrey Wagner for technical support. Dr. Jennell Miller's artistic efforts in generating portions of Figures 1, 3, and 6 are especially appreciated and her permission to use these drawings is acknowledged. A portion of this work was supported by a Biomedical Research Infrastructure Network grant awarded to the University of Nevada.

2.10 Salivary Gland Development and Programmed Cell Death

D J Andrew and M M Myat, Johns Hopkins University School of Medicine, Baltimore, MD, USA

2.10.1. Introduction

Insect salivary glands are instrumental in the spread of diseases that affect humans, livestock, and agricultural crops. For example, the salivary glands of the mosquito vector *Anopheles gambiae* harbor and transmit the infectious *Plasmodium falciparum*, the microorganism causing malaria (Ghosh *et al.*, 2000). Similarly, the salivary glands of the western black-legged tick *Ixodes pacificus* harbor the spirochetal bacterium *Borrelia burgdorferi*, which is responsible for Lyme disease (Crippa *et al.*, 2002). Salivary glands have also been implicated in the transmission of Dengue fever and leishmaniasis from their insect vectors to both humans and livestock. Plant viruses, such as the tomato spotted wilt virus, are also transmitted through the salivary glands of insect hosts (Kritzman *et al.*, 2002). Termite salivary glands produce the cellulolytic enzymes required to digest wood products, leading to the deterioration of many manmade structures.

Despite their critical roles both in disease and in economic enterprises, very little is known about the specification and formation of salivary glands in most insect species, the one exception being the salivary glands of *Drosophila melanogaster.* In this chapter, the early development of insect salivary glands and salivary gland histolysis during metamorphosis are reviewed. Focus is placed on the specification and morphogenesis of the *Drosophila* salivary gland, drawing parallels with silk gland development in *Bombyx mori*, which appears to use a similar regulatory hierarchy for its specification and early morphogenesis (see **Chapter 2.11**). The molecular and cellular changes associated with *Drosophila* salivary gland destruction during metamorphosis are also reviewed, and limited studies on salivary gland histolysis in other insects, which suggest a common mechanism for salivary cell death, are discussed. A brief synopsis of salivary gland physiology and its relation to human disease is also presented and discussed. The parallels in gene expression in structures as divergent as the *Drosophila* salivary gland and the *Bombyx* silk gland suggest that the cellular and molecular mechanisms underlying *Drosophila* salivary gland specification, morphogenesis, and physiological specialization are likely to be shared among the salivary glands of all insect species. A list of the genes that are involved in the specification and morphogenesis of the *Drosophila* salivary gland is given in the appendix at the end of this chapter.

2.10.2. Specification of the *Drosophila* Salivary Gland Primordia

2.10.2.1. Introduction to *Drosophila* Salivary Glands

The embryonic/larval salivary gland of *D. melanogaster* is a relatively simple tubular organ composed

of three functional cell types, the duct and secretory cells, which function during embryonic and larval stages, and the imaginal ring cells, which give rise to the adult salivary gland during metamorphosis. The secretory cells form paired elongated tubular glands that are positioned adjacent to the lateral body wall muscles of the thorax. These cells synthesize and secrete protein beginning in the early embryonic stages and continuing throughout the larval stages. Levels of protein synthesis and secretion increase dramatically just prior to metamorphosis, when the secretory glands make the glue proteins, which are required for adhesion of the larva to solid substrates prior to pupariation. The salivary duct is a Y-shaped tubular structure with two individual ducts, which connect to the secretory tubes, and a central common duct, which connects the individual ducts to the mouth. The duct cells form a conduit, which carries the secretory gland secretions to the larval mouth. The imaginal ring cells, the precursors to the adult salivary gland, form a ring of cells located between the proximal ends of the secretory tubes and the distal ends of the individual duct tubes with proximal being closest to the embryo's ventral surface.

All of the cells that give rise to the embryonic/larval and adult salivary gland derive from ventral ectodermal cells located in a posterior region of the head, a domain known as parasegment 2. Once specified, secretory gland precursor cells cease normal cell division and instead grow by an increase in individual cell size. To accommodate the increased metabolic needs of the large secretory cells, the chromosomes undergo a special form of polyploidization, known as endoreduplication (review: Edgar and Orr-Weaver, 2001). In this process, the DNA strands replicate but fail to separate, ultimately creating the giant polytene chromosomes, which have been extensively used for mapping deficiencies, chromosomal rearrangements, cloned genes, and protein binding sites. Like the salivary secretory cells, the duct cell chromosomes are also polytenized, although to a lesser extent than the secretory cells (review: Edgar and Orr-Weaver, 2001). In contrast, the imaginal ring cells remain diploid, continuing to divide during the larval stages.

Since normal mitotic cell divisions cease once the cells are specified and because the salivary gland cells do not normally undergo programmed cell death during morphogenesis, duct and secretory cell numbers remain constant throughout morphogenesis and the subsequent larval stages (Campos-Ortega and Hartenstein, 1997). This constancy in cell number greatly simplifies studies of the cellular events of invagination, tube elongation, and directed migration, which are required to form a normally shaped and properly positioned salivary gland. The salivary gland that forms during embryogenesis functions throughout the three larval stages and into the early prepupal stage. In the early prepupal stage, the *Drosophila* salivary glands undergo programmed cell death in response to ecdysone pathway activation in the absence of juvenile hormone (Jiang *et al*., 2000). The larval salivary glands are ultimately replaced by the adult salivary gland, which forms from the imaginal ring cells.

2.10.2.2. Anterior–Posterior Determinants

The *Drosophila* salivary glands derive entirely from the ventral portion of the ectoderm that spans a domain known as parasegment 2 (PS2). All cells that form the embryonic/larval salivary gland express the homeotic transcription factor gene *Sex combs reduced* (*Scr*) (see **Chapter 1.8**) and *Scr* is absolutely required for salivary gland formation (Panzer *et al*., 1992; Andrew *et al*., 1994). In the absence of *Scr* function, salivary glands fail to form, and when *Scr* is expressed in new places in the embryo, additional salivary glands form in other (para)segments (Panzer *et al*., 1992; Andrew *et al*., 1994). Formation of additional salivary glands in other domains due to ectopic expression of *Scr* is limited, however, to PS0 and PS1 due to the expression of other salivary gland-repressing genes that are expressed in posterior segments (Andrew *et al*., 1994). In the region spanning PS3–PS13, the zinc finger transcription factor gene *teashirt* (*tsh*) blocks ectopic salivary gland formation (Andrew *et al*., 1994) and, in PS14, the homeotic transcription factor gene, *Abdominal-B* (*Abd-B*) (see **Chapter 1.8**), blocks salivary gland formation (Andrew *et al*., 1994). Thus, localized expression of homeotic proteins and other transcription factors limits salivary gland formation to PS2, which approximately coincides with the labial segment, the most posterior segment of the head (**Figure 1a**).

Salivary gland formation also requires two other homeodomain-containing transcription factor genes, both of which are expressed relatively ubiquitously in the early embryo (Henderson and Andrew, 2000). Loss of maternal and zygotic function of *extradenticle* (*exd*) or zygotic loss of function of *homothorax* (*hth*) result in the complete failure of salivary gland formation, as is observed with loss of *Scr* (Henderson and Andrew, 2000). Thus, Scr, Exd, and Hth (see **Chapter 1.8**) are likely to work as a transcriptional complex controlling gene expression in the salivary gland (Ryoo and Mann, 1999; Ryoo *et al*., 1999).

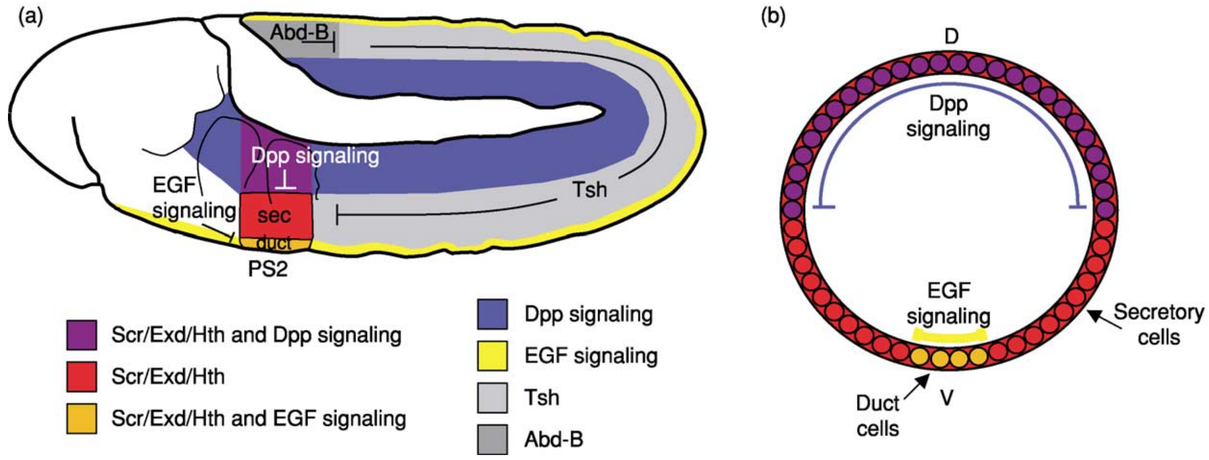

Figure 1 Genes controlling the specification, positioning, and number of salivary gland cells in *Drosophila*. (a) A schematic lateral view of a stage 11 embryo. (b) A schematic cross-section through parasegment 2 (PS2) depicting only ectodermal cells. The salivary gland fate is specified by the positive activities of Scr, which is expressed throughout the PS2 ectoderm, and the more ubiquitously expressed transcription factors, Exd and Hth (red background in (b)). Dpp signaling along the dorsal (D) region of the embryo blocks Scr/Exd/Hth activation of salivary gland gene expression in these cells (blue and purple in (a) and (b)), thus limiting salivary gland precursors to the ventral ectoderm of PS2. When *Scr* is ectopically expressed during development, Tsh and Abd-B (gray and dark gray in (a), respectively) block Scr/Exd/Hth activation of salivary gland fates in posterior regions of the embryo. Epidermal growth factor (EGF) signaling (yellow and orange in (a) and (b) in the ventral cells (V) blocks Scr/Exd/Hth activation of secretory cell-specific genes, including *fkh*. Expression of *fkh* (not shown) blocks expression of duct-specific genes in the secretory cells. Since the salivary gland precursors cease dividing once specified and do not normally undergo programmed cell death during their development, the same process that specifies the salivary gland fate also determines the number of cells in this organ. (Reproduced with permission from Bradley, P.L., Haberman, A.S., Andrew, D.J., **2001**. Organ formation is *Drosophila*: Specification and morphogenesis of the salivary gland. *BioEssays 23*, 901–911; © John Wiley & Sons, Inc.)

Expression of *Scr* and *hth* and the nuclear localization of Exd disappear shortly after the salivary gland cells have begun to internalize to form the secretory tubes (Henderson and Andrew, 2000). This change in gene expression and protein localization is due to repression of *hth* expression in the salivary gland by Scr/Exd/Hth. Shutting off *hth* expression in the salivary glands results in a loss of nuclear Exd since Exd requires Hth to block its nuclear export (Rieckhof *et al*., 1997; Pai *et al*., 1998; Abu-Shaar *et al*., 1999; Jaw *et al*., 2000). *Scr* expression disappears in the invaginating salivary gland as well, since maintenance of its transcription in the ventral ectoderm of PS2 requires *exd* and *hth* (Henderson and Andrew, 2000). Thus, Scr and its cofactors, Exd and Hth, are required to specify but not maintain a salivary gland fate, and these proteins act together to activate and repress gene expression in the salivary gland.

2.10.2.3. Dorsal–Ventral Determinants

Although all of the PS2 ectoderm initially expresses Scr and its cofactors, Exd and Hth, only the ventral ectodermal cells become salivary gland. Dorsal cells within PS2 do not form salivary glands due to activation of the Decapentaplegic (Dpp) signaling cascade (Panzer *et al*., 1992; Henderson *et al*., 1999). Expression of *dpp* is restricted to the dorsal half of the embryo (Figure 1b) through repression by the Dorsal transcription factor, which is nuclear in only ventral cells due to earlier signaling events under the control of maternally encoded gene products (Morisato and Anderson, 1995). Loss-of-function mutations in *dpp*, or in any of the genes encoding the downstream signaling components, lead to the expression of salivary gland genes throughout the PS2 ectoderm (Panzer *et al*., 1992; Henderson *et al*., 1999). Conversely, ectopic expression of *dpp* throughout the embryo, including the ventral cells of PS2, can repress expression of all tested salivary gland genes. Mutations in *brinker* (*bri*), which encodes a nuclear protein that blocks transcription of Dpp target genes and thus limits the extent of Dpp signaling (Affolter *et al*., 2001), result in smaller salivary gland primordia (Lammel and Saumweber, 2000; Torres-Vazquez *et al*., 2001).

Overall, the combination of localized expression of transcription factors, including Scr, Tsh, and Abd-B, and localized Dpp signaling limits salivary gland formation to the ventral ectodermal cells of PS2 (Figure 1b). Since these cells neither divide nor die during salivary gland formation, these factors simultaneously determine both the position and number of cells that comprise the entire embryonic/larval salivary gland.

2.10.2.4. Determinants of Cell Types within the Primordium

The distinction between duct and secretory primordia within the salivary gland is controlled by epidermal growth factor (EGF) signaling (**Figure 1**) (Panzer *et al.*, 1992; Kuo *et al.*, 1996). In *Drosophila*, most components of the EGF signaling pathway are expressed in all cells (Shilo, 2003). Localized activation of the EGF pathway is mediated by localized expression of *rhomboid* (*rho*), which encodes a resident transmembrane endoplasmic reticulum protein required for the processing of the secreted Spitz (Spi) ligand of the EGF receptor (Urban *et al.*, 2001; Tsruya *et al.*, 2002). The most ventral ectodermal cells express *rho*, leading to the subsequent release of the active ligand along the ventral ectodermal midline, which diffuses two to three cell diameters to activate the EGF receptor (EGFR). Salivary cells that receive sufficient levels of the EGF signal adopt a duct cell fate whereas cells positioned more laterally (away from the source of processed ligand) adopt a secretory cell fate. EGF signaling works, at least in part, by blocking the expression of secretory-specific genes in the salivary duct. One such gene is *fork head* (*fkh*), which itself encodes a transcription factor whose expression is normally limited to secretory cells (Kuo *et al.*, 1996). In the secretory cells, Fkh blocks expression of all duct-specific genes tested so far, including *trachealess* (*trh*), *Serrate* (*Ser*), and *dead ringer* (*dri*), three genes whose expression in the duct is independent of the others (Haberman and Andrew, 2003). The *trh* gene encodes a transcription factor expressed in duct cells and required for these cells to invaginate and form tubes (Isaac and Andrew, 1996). *Ser* encodes a Notch ligand required to specify a third cell type within the salivary gland (see below) and *dri* encodes another transcription factor whose role in the duct is not yet known (Haberman and Andrew, 2003).

Subsequent signaling between the duct and secretory cell primordia specifies the adult salivary gland cell precursors, the imaginal ring cells (Haberman and Andrew, 2003). During metamorphosis, the imaginal ring cells will replace the larval salivary glands, which undergo programmed cell death in response to ecdysone (Jiang *et al.*, 1997). Among the genes expressed in the salivary duct primordia is *Ser* (Kuo *et al.*, 1996), which encodes one of two known transmembrane ligands for Notch (Fleming *et al.*, 1990; Thomas *et al.*, 1991). Notch, a transmembrane receptor protein regulating numerous cell fate decisions, is expressed relatively ubiquitously but is transiently upregulated in the salivary gland secretory cell primordia prior to internalization (Kidd *et al.*, 1989). Although adequate markers do not yet exist to identify the imaginal cells in the early embryonic salivary gland, these cells express at least one tissue-specific gene in late embryos, known as *Tetraspanin74F* (*Tsp74F*), and are also easily distinguished in second instar larvae on the basis of their smaller nuclear size. The imaginal cells have smaller nuclei because these cells remain diploid throughout larval life and do not become polytenized as do the adjacent larval duct and secretory cells. In *Ser* mutants, expression of *Tsp74F* is absent in the region of the adult imaginal ring precursors in late embryos. Moreover, the imaginal cell population is missing in *Ser* mutant second instar larvae. These findings suggest that Ser in the duct cell primordia signals to the adjacent secretory primordia to specify the imaginal ring cell fate (Haberman and Andrew, 2003). In the absence of the Ser signal, cells adopt a default state, which is to form secretory cells. Thus, early EGF signaling distinguishes the two cell populations that form the larval salivary gland, duct versus secretory cells (**Figure 1**). Subsequently, duct-specific *Ser* expression activates the Notch pathway in the immediately adjacent secretory cells, specifying the precursors to the adult salivary gland.

Even within the apparently homogeneous duct and secretory primordia, additional subdomains of gene expression are evident (Jones *et al.*, 1998; Myat and Andrew, 2000a; Zhou *et al.*, 2001). In the duct primordia, these subdomains distinguish the more posterior individual duct precursors from the more anterior common duct precursors (Jones *et al.*, 1998). Although in the secretory portion of the gland, subdomains of gene expression do not correlate with obvious differences in cell type or tube dimensions, they do correlate with the order in which the cells internalize (Myat and Andrew, 2000a, 2002; Zhou *et al.*, 2001). The subdomains of gene expression within the salivary gland primordia reveal additional, perhaps more subtle input from both dorsal–ventral determinants, such as the EGF and Dpp signals, and from segment polarity genes, which are differentially expressed and/or activated along the anterior–posterior axes within individual parasegments.

2.10.3. Morphogenesis of the Salivary Gland

2.10.3.1. Secretory Cell Internalization and Tube Formation

The secretory primordia of the salivary gland form two ectodermal plates of columnar epithelial cells

known as the salivary gland placodes. The cells within each placode undergo a series of shape changes to internalize and form elongated tubes. Cell shape change is accompanied by basal migration of nuclei and constriction of the apical surfaces, which occurs in a regulated, sequential manner beginning with cells in the dorsal–posterior domain, then in dorsal–anterior, then ventral–anterior and, finally, the ventral–posterior domain (Myat and Andrew, 2000a) (**Figure 2**). Apical constriction of salivary gland cells requires *fkh* (Myat and Andrew, 2000b), an early salivary gland gene directly regulated by Scr and Exd (Ryoo and Mann, 1999). In the absence of *fkh* function, the nuclei move to a basal position in the cells but the cells remain approximately columnar instead of forming the pyramidal-shaped cells observed in wild-type salivary glands (Myat and Andrew, 2000b). Either as a cause or consequence of the failure to undergo this shape change, the secretory cells fail to internalize and form tubes in *fkh* mutants (**Figure 3a**). Interestingly, *fkh* is also required to prevent apoptotic cell death in the salivary gland primordia (Myat and Andrew, 2000b). In *fkh* mutants, expression of both *reaper* (*rpr*) and *head involution defective* (*hid*), two of the known positive effectors of programmed cell death (see also **Chapter 2.10**), are activated in the secretory cells prior to internalization. The secretory cells of *fkh* mutants die, exhibiting features of an apoptotic cell death. Furthermore, *fkh* mutant salivary glands can be rescued from death simply by deleting the genes encoding the positive activators of programmed cell death (**Figure 3a**).

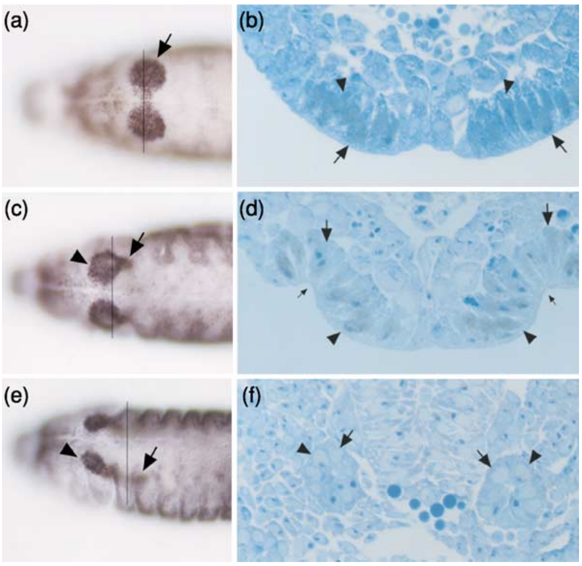

Figure 2 Morphogenesis of the secretory tubes of the *Drosophila* salivary gland. Embryos in (a), (c), and (e) were stained for dCREB-A to visualize the nuclei of secretory cells. Panels (b), (d), and (f) are representative cross-sections of invaginating salivary cells at the embryonic stages corresponding to those in (a), (c), and (e), respectively. The line through each salivary gland in (a), (c), and (e) indicates the approximate region from which the corresponding cross-sections were obtained. Prior to invagination (a), when all secretory cells are found at the ventral surface of the embryo, the cells are columnar (b) with nuclei located randomly in the apical (arrow) or basal (arrowhead) domains. When cells in a dorsal–posterior region of the placode begin to invaginate (c, arrow), an invagination pit is formed (d, small arrow) consisting of pyramidal shaped cells with nuclei coordinately located in a basal position (d, large arrow) in contrast to noninvaginating cells (d, arrowhead) that remain columnar and have randomly positioned nuclei. Towards the end of invagination, when most secretory cells are internalized (e, arrow), an elongated secretory tube is formed (e and f, arrows) consisting of a single layer of wedge-shaped cells surrounding a central lumen.

Once the secretory cells have invaginated in wild-type embryos, they generate a large amount of apical membrane elongated in the proximal–distal axis of the salivary gland tube. Apical membrane generation at this postinvagination step is critical to achieving the final shape of the gland. In mutants where either too little or too much apical membrane is produced, the shape of the secretory tubes is altered significantly (Myat and Andrew, 2000a, 2002). As a consequence of limited apical membrane growth, *huckebein* (*hkb*) mutants form short, dome-shaped glands instead of the elongated tubes that characterize the secretory tubes of wild-type embryos (**Figure 3a**). In *hairy* (*h*) mutants, excessive apical membrane is formed leading to either branched salivary glands or salivary glands with expanded lumina (**Figure 3a**). The salivary glands of *h-hkb* double mutant flies look identical to those of *hkb* mutants, indicating that *hkb* function is required for the apical expansion observed in the *hairy* mutants.

The *hkb* gene encodes a zinc finger transcription factor (Brönner *et al.*, 1994) that regulates membrane growth, at least in part, through two downstream target genes (Myat and Andrew, 2002) (**Figure 4**). One target is *crumbs* (*crb*), an apical membrane protein required for apical membrane specification and growth (Tepass *et al.*, 1990, 1996; Wodarz *et al.*, 1995; Izaddoost *et al.*, 2002; Pellikka *et al.*, 2002). The other target is *klarsicht* (*klar*), a putative regulator of dynein ATPase proposed to promote minus-end directed microtubule-dependent organelle transport (Fischer-Vize and Mosley, 1994; Welte *et al.*, 1998; Mosley-Bishop *et al.*, 1999). Loss of *klar* function results in salivary gland shapes similar to those of *hkb* mutants and overexpression of *klar* leads to the same branching and bulging phenotypes observed with *hairy* mutations (Myat and Andrew, 2002). Expression of

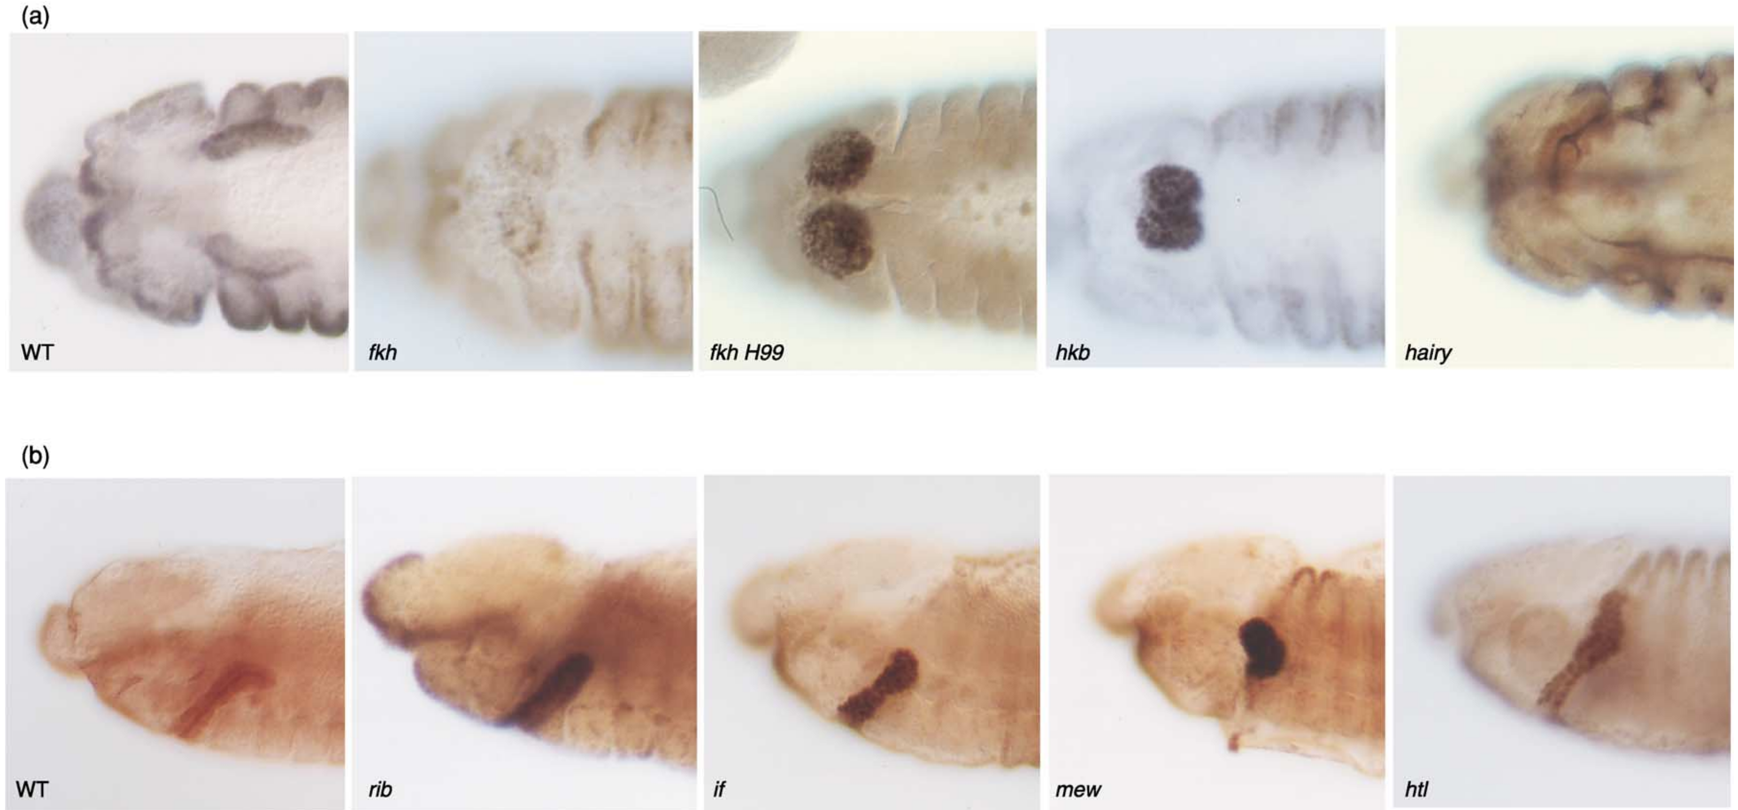

Figure 3 (a) Mutations affecting secretory cell invagination and tube elongation in the *Drosophila* salivary gland. All embryos were stained for dCREB-A except for *hairy*, which was also stained for Crumbs to visualize the salivary gland lumen. In contrast to wild-type (WT) embryos that form elongated secretory tubes, *fkh* embryos do not form secretory tubes because the secretory cells fail to invaginate and instead die by apoptosis. In *fkh H99* embryos, where apoptosis is inhibited, salivary secretory cells still fail to invaginate and remain at the ventral surface of the embryo. In *hkb* embryos, dome-shaped salivary glands are formed, and in *hairy* embryos, branched salivary glands are formed. (b) Mutations affecting migration and final placement of the Drosophila salivary glands. All embryos were stained for dCREB-A. In wild-type embryos, the salivary gland that was initially oriented dorsally turns and migrates posteriorly. In contrast, in *rib, if*, and *mew* embryos, the salivary gland fails to migrate. In *htl* embryos, where formation of the visceral mesoderm is disrupted, the salivary gland migrates further dorsally.

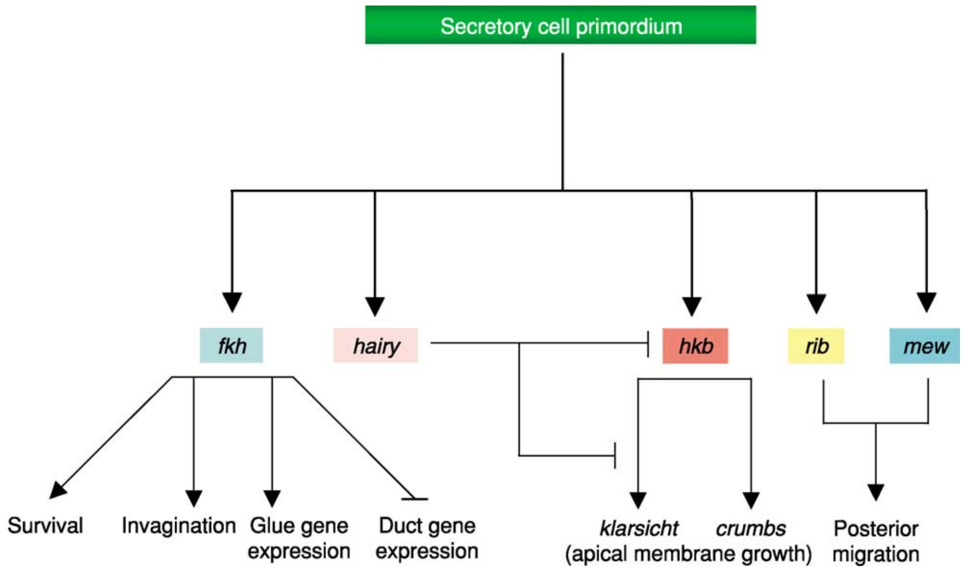

Figure 4 Regulatory network controlling formation of the secretory portion of the salivary gland. Among the earliest expressed genes in the *Drosophila* salivary gland are the transcription factor genes, *fkh, hairy, hkb*, and *rib*, as well as an α-integrin subunit gene, *mew* (also known as α*PS1*). Fkh, Hairy, and Hkb are required for normal invagination and elongation of the secretory tube, whereas Rib and Mew are required for posterior migration of the secretory tube. Fkh is also required for secretory cell survival, expression of glue protein genes in late third instar larvae, and repression of duct-specific genes in the secretory cells. Hairy represses expression of *hkb* and *klar*. Hkb activates expression of *crb* and *klar*, which are required for the generation and delivery of apical membrane, respectively.

wild-type *klar* in *hkb* mutants partially rescues tube elongation. Overexpression of *crb* throughout wild-type salivary glands causes expansion of the salivary gland lumina just like overexpression of *hkb*. In the experiments overexpressing *crb* RNA, high level accumulation of the Crb protein is observed only in cells that also express high levels of wild-type *hkb*, unless either *hkb* or *klar* are also overexpressed.

Based on the genetic interaction studies as well as gene expression patterns in *hairy* mutants, wild-type Hairy is proposed to limit the amount of both Hkb and Klar by repressing expression of both genes shortly after their expression is initiated in the salivary gland primordia (Figure 4). The transient, highly regulated expression of *hkb* and its target genes is thus critical to forming the simple, unbranched, and elongated secretory tubes observed in wild-type embryos.

2.10.3.2. Secretory Cell Migration and Positioning

Once the secretory cells have internalized and cells of the tube have contacted the layer of cells surrounding the developing gut, known as the visceral mesoderm (VM), the cells turn and migrate posteriorly. This posterior migration is required to position the secretory tubes with their long axes parallel to the anterior–posterior axis of the embryo. Posterior migration of the salivary gland requires wild-type function of the *ribbon* (*rib*) gene, integrin signaling, and an intact VM. In embryos mutant for *rib*, the secretory cells internalize normally and form tubular organs. However, the tubes fail to migrate past the point at which wild-type salivary gland cells normally initiate posterior migration (Bradley and Andrew, 2001) (**Figure 3b**). The salivary duct cells of *rib* mutants also fail to elongate and form tubes. *rib* mutants show migration defects in other tissues, including the tracheae, where migration of most branches is delayed and migration of the dorsal trunk cells, which normally occurs along the anterior–posterior body axis, fails entirely. The *rib* gene encodes a nuclear BTB/POZ protein with weak homology to the DNA-binding domains of the Pipsqueak family of transcription factors and the Rib protein contains seven consensus sites for mitogen-activated protein kinase (MAPK) phosphorylation (Bradley and Andrew, 2001; Shim *et al*., 2001). Based on its phenotypes in other tissues, including the trachea, epidermis, and Malphigian tubules (Blake *et al*., 1998; Bradley and Andrew, 2001; Shim *et al*., 2001; see also **Chapters 2.7** and **2.8**), Rib may function to integrate signals from both Wingless and MAPK pathways to mediate changes in cell shape, both during migration and in the fully formed organs.

Mutations in integrin signaling show defects in secretory tube migration very similar to those observed with mutations in *rib* (Bradley *et al*., 2003).

Salivary glands of embryos homozygous for either *multiple edematous wings* (*mew*), which encodes an integrin α-subunit expressed in the secretory cells (Brower *et al*., 1995), or *inflated* (*if*), which encodes another integrin α-subunit expressed in all mesoderm (Bogaert *et al*., 1987), completely fail to migrate past the initial point of contact between secretory cells and the VM (Bradley *et al*., 2003) (**Figure 3b**). However, perhaps because the duct tubes form normally in the integrin mutants and continue to internalize, the secretory tubes of integrin mutants often buckle forming U-shaped tubes with the tips of the tubes directed anteriorly. In the complete absence of integrin function, a situation created either by simultaneously removing function of both α-subunits expressed in the salivary gland (*mew* and *scabrous* (*sca*)) or by removing both the maternal and zygotic function of the essential β-subunit (Brown *et al*., 2000), defects similar to loss of only *mew* or *if* are observed (Bradley *et al*., 2003). The secretory cells internalize and form elongated tubes, but fail to migrate posteriorly. Thus, internalization and formation of the secretory tubes occur in the complete absence of integrin function and may be mediated entirely by cell shape change. This finding suggests that cell migration may be required only at later stages to properly position the secretory tubes within the embryo.

Mutations in genes that disrupt the physical integrity of the VM suggest a role for this tissue in both the initiation of posterior salivary gland migration and in providing a suitable migration substrate for continued posterior movement. In *heartless* (*htl*) or *heartbroken* (*hbr*) mutants, which encode one of the two known fibroblast growth factor (FGF) receptors in *Drosophila* and a downstream effector, respectively, not all of the VM precursors migrate to their final position (Bradley *et al*., 2003) (**Figure 3b**). The defect in cell migration leads to a discontinuous layer of mesodermal cells around the forming gut (Shishido *et al*., 1993; Beiman *et al*., 1996; Gisselbrecht *et al*., 1996; Michelson *et al*., 1998; Iman *et al*., 1999). Salivary gland migration in the *htl* and *hbr* mutant embryos occurs, but is frequently aberrant (Bradley *et al*., 2003). At early stages, when expression of VM markers is easily followed, the migration defects in the FGF signaling mutants correlate with breaks in the VM.

Very similar salivary gland migration defects are observed in *thick veins* (*tkv*) mutants, where breaks are also observed in the VM (Bradley *et al*., 2003). The *tkv* gene encodes one of the essential receptors for Dpp (Nellen *et al*., 1994) and Dpp signaling is required to specify a subset of VM precursors (review: Frasch, 1999).

In *tinman* (*tin*) mutants, where the VM is not properly specified (Azpiazu and Frasch, 1993) and only the most anterior portion of the VM forms, the secretory cells initiate posterior migration but migrate dorsally off course at the point where the VM ends (Bradley *et al*., 2003).

The migration defects observed with mutations in FGF signaling, Dpp signaling, and Tin indicate that an intact VM is required to form secretory tubes that are fully elongated along the anterior–posterior body axis. These phenotypes, combined with the phenotypes observed with mutations in the integrin genes, indicate that the VM functions both as a physical barrier and as a suitable substrate for migration. However, to perform these functions, it is not necessary for the VM precursor cells to differentiate fully into VM. In *biniou* (*bin*) mutants, the VM cells fail to express markers that distinguish VM from other mesoderm and many of the VM precursors appear to take on a somatic mesodermal fate (Zaffran *et al*., 2001). Nonetheless, posterior migration of secretory cells in *bin* mutants is normal (Bradley *et al*., 2003).

Studies of the salivary gland genes expressed in the early secretory tubes indicate roles for these genes in morphogenesis (**Figure 4**). Fkh, Hairy, Hkb, and their downstream target genes are required to form simple, unbranched, and elongated secretory tubes (Myat and Andrew, 2000a, 2000b, 2002). Rib and Mew are required for posterior migration of the secretory tubes, a process necessary to position the tubes along the anterior–posterior axis of the embryo (Bradley and Andrew, 2001; Bradley *et al*., 2003). Additional tissue–tissue interactions and signaling pathways are likely to be required for posteriorly directed movement and for later stages of tube positioning.

2.10.3.3. Salivary Duct Formation

Although much is known about the events controlling the formation of the secretory portion of the *Drosophila* salivary gland, less is known about the events underlying salivary duct formation. The duct forms from two to three rows of ectodermal cells flanking each side of the ventral midline of PS2. Cells in the posterior half of the duct primordium form the individual ducts, whereas cells in the anterior half form the common duct. The individual ducts internalize first, immediately following the internalization of the secretory cells (**Figure 5**). Once the individual ducts have fully internalized and formed tubes, the common ducts internalize to form the central common tube that connects the individual ducts to the larval mouth. Considerable cell rearrangements occur during formation of the salivary duct, leading to the suggestion that salivary

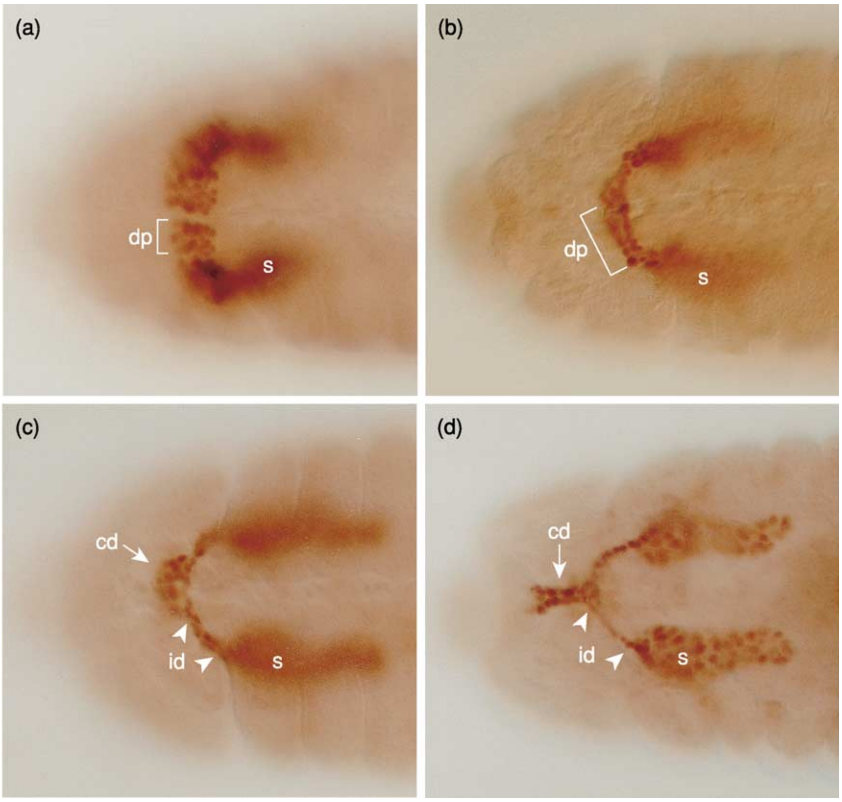

Figure 5 Morphogenesis of the salivary gland duct. *Drosophila* embryos carrying a *P* element insertion in the *trh* gene were stained with an anti-β-galactosidase antibody to visualize all salivary gland cells. All views are from the ventral surface with the secretory cells (s) typically out of focus. (a) The duct primordium (dp; one half is bracketed) remains on the embryo surface when the secretory cells have internalized. (b) During stage 12, the duct primordia become narrower along the anteroposterior axis and elongate laterally. (c) By stage 13, the individual ducts (id) have fully internalized and formed tubes. The common duct (cd) precursors begin to elongate along the anteroposterior axis. (d) The common duct tube forms by embryonic stage 14. (Reproduced with permission from Bradley, P.L., Haberman, A.S., Andrew, D.J., **2001**. Organ formation is *Drosophila*: Specification and morphogenesis of the salivary gland. *BioEssays 23*, 901–911; © John Wiley & Sons, Inc.)

ducts form by the process of convergent extension (Jones *et al*., 1998). Convergent extension is defined as a change in the shape of an organ or group of cells that is mediated by cell intercalation (Keller, 2002).

Among the genes known to be expressed and/or required in the salivary duct are several encoding putative transcription factors, including *trachealess* (*trh*), *eyegone* (*eyg*), and *dead ringer* (*dri*) (**Figure 6**). Additional duct-expressed genes include *Serrate* (*Ser*), which encodes a Notch ligand, and *breathless* (*btl*), which encodes an FGF receptor homolog. Of these genes, only a subset has been shown to be required for normal duct formation. The *trh* gene, which encodes a bHLH-PAS family transcription factor, is required for the duct cells to invaginate and form tubes (Isaac and Andrew, 1996). Much like the *trh* mutant phenotypes observed in other Trh-expressing cells (the trachea and filzkörper, posterior tubes lined with cuticular threads that function as filters for the trachea), the duct precursor cells in *trh* mutants fail to undergo any of the morphological changes of tube formation and simply remain on the embryo surface at their site of origin.

As a transcription factor, Trh must regulate tube formation through the transcriptional regulation of downstream target genes. Among the downstream target genes is *btl* (Ohiro and Saigo, 1997; Sonnenfeld *et al*., 1997; Zelzer *et al*., 1997), which is required for migration of all of the branching tubes of the tracheal system (Klämbt *et al*., 1992; Reichman-Fried *et al*., 1994) (**Figure 6**). However, despite its Trh-dependent expression in the salivary duct, the salivary duct appears normal in *btl* mutant embryos. Another reported Trh target gene is *eyg*, whose expression in late embryos is limited to the individual duct and proximal secretory cells, including the cells that normally form the imaginal ring (Jones *et al*., 1998). Due to the absence of specific loss-of-function mutations in *eyg*, functional studies on *eyg*'s role in salivary duct formation have been limited to embryos either homozygous for

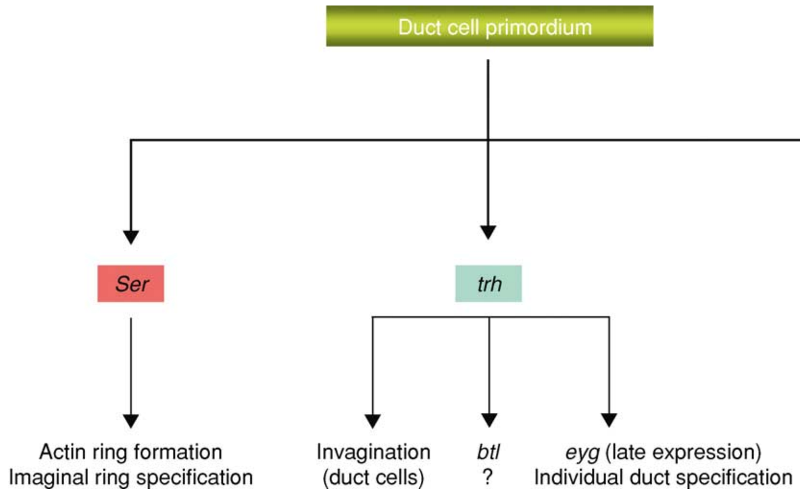

Figure 6 Regulatory network controlling the formation of the duct portion of the salivary gland. Among the earliest expressed genes in the salivary duct of *Drosophila* are two transcription factor genes, *trh* and *dri*, and the gene encoding a transmembrane Notch ligand, *Ser*. Trh is required for invagination and tube formation in the salivary duct, trachea, and filzkörper, and is required for the expression of two downstream duct genes, *btl* and *eyg*. The *eyg* gene has been implicated in specification of the individual ducts. Mutations in *btl* and *dri* do not lead to detectable defects in the salivary duct. *Ser* is required for actin ring formation on the apical surface of the salivary duct and for specification of the adult salivary gland primordia, known as the imaginal ring cells.

a small deficiency removing an estimated 20 genes, and embryos carrying the deficiency in *trans* to an inversion that maps near the *eyg* gene. Embryos of both genetic compositions show defects in duct formation that suggest a role for *eyg* in distinguishing the individual ducts from the common duct (Kuo *et al*., 1996). Similarly, a failure to observe imaginal ring cells associated with the unattached secretory portions of the glands has been interpreted to reflect an additional requirement for *eyg* in specifying this cell type. Expression of a transgene carrying the *eyg* cDNA under the control of a heat shock-inducible promoter partially rescues the individual duct phenotypes observed in homozygous mutant embryos, although the imaginal ring cells of these same animals were not examined. The assignment of a role for *eyg* in individual duct and imaginal ring specification is further complicated by the existence of a close *eyg* homolog, known as *twin of eyegone* (*toe*), which maps immediately adjacent to *eyg* on the third chromosome and is expressed in a very similar pattern in the salivary gland. Thus, it is unclear whether the salivary duct phenotypes observed in the *eyg* mutant backgrounds are solely due to loss of *eyg* function.

Two of the known duct genes, *Ser* and *dri*, are expressed in the duct cells of *trh* mutants to wild-type levels as is *trh* itself, indicating that Trh does not control expression of all duct-specific genes. The *dri* mutants have apparently normal salivary ducts, suggesting either a very subtle role for *dri* in this tissue or some redundancy in its function. Alternatively *Ser* mutants, exhibit a loss of imaginal ring cells, as discussed earlier, and lack the apical actin rings that are observed in wild-type salivary ducts of early larvae (Haberman and Andrew, 2003). These apical actin rings may be precursors of taenidial-like structures observed in the late third instar salivary ducts. In the trachea, taenidia are a series of epithelial folds thought to provide both strength and flexibility. The related structures in the salivary duct may serve a similar function.

2.10.4. Specification and Formation of the *Bombyx* Silk Gland

The silk glands of *Bombyx mori* (see **Chapter 2.11**) are thought to be evolutionarily homologous to the salivary glands of *Drosophila* since they develop from the same embryonic segment and their formation correlates with the expression of the *Bombyx* homolog of the homeotic gene *Scr* (see **Chapter 2.11**). The *Bombyx* silk gland invaginates from the ventral ectoderm of the labial segment to form a tubular structure that elongates and moves into the embryo until the distal end of the gland reaches a muscle in abdominal segment 6 (Matsunami *et al*., 1999). The posterior portions of the gland also associate tightly with the visceral branches of the trachea. Once the silk gland becomes associated with the abdominal muscle and trachea, it curls slightly as it continues to elongate. After the silk gland primordial cells have invaginated, the cells rearrange to form two orderly rows of cells throughout the length of the gland. Unlike the *Drosophila*

salivary glands, the silk gland cells continue to divide during invagination and tube elongation. Even after cell division ceases, the cells continue to enlarge. In the mature silk gland, there are approximately 250 cells in the anterior silk gland (ASG), 200 cells in the middle silk gland (MSG), and 450 cells in the posterior silk gland (PSG). Cells of the MSG and PSG are involved in the secretion of silk proteins and the ASG cells are likely to act in their transport. Based on their distinct roles and their respective gene expression patterns (see below and **Chapter 2.11**), it appears that the *Bombyx* ASG is equivalent to the *Drosophila* salivary duct whereas the MSG and PSG are equivalent to the *Drosophila* secretory glands (**Figure 7**).

Interestingly, some of the homologs of major players of *Drosophila* salivary gland development are expressed in the *Bombyx* silk gland, including *Scr*, *fkh*, and *trh*. Moreover, *Bombyx* Scr may activate *Bombyx fkh* expression as occurs in the *Drosophila* salivary gland; this regulatory interaction is, however, likely to be indirect (Kokubo *et al*., 1997) unlike in *Drosophila* (Ryoo and Mann, 1999). In the *Nc* mutant, which is a deletion of the sequences encoding the homeodomain of the *Bombyx Antennapedia* gene, *Bombyx Scr* and *fkh* expression are observed in new places. In *Nc/Nc* homozygotes, the *Bombyx Scr* gene is ectopically expressed in three posterior thoracic segments, T1, T2, and T3. In these *Nc/Nc* mutants, small invaginating structures resembling the silk glands form in T1–T3. Just as expression of the *Bombyx Scr* gene disappears in the invaginating cells of the *Nc/Nc* mutants, the *Bombyx fkh* gene is activated in the same cells, with the same timeline as is observed in the normal silk gland. These studies suggest that although *fkh* expression in the silk gland may be activated by Scr, the delayed expression of *fkh* relative to Scr indicates a role for some intermediate molecule.

The *Bombyx trh* gene is very similar to its *Drosophila* homolog, with 100% identity in the bHLH domain, 97% homology in the PAS-A domain, and 80% homology in the PAS-B domain (Matsunami *et al*., 1999). Like the *Drosophila* gene, *Bombyx trh* is initially expressed in all cells of the early silk gland, but becomes restricted to the ASG and MSG at later stages. Strong staining persists in the ASG with only weak staining in the MSG. The *Bombyx trh* gene is also, not surprisingly, expressed in the entire trachea from the primordial stages and throughout embryogenesis, as is its *Drosophila* homolog. The expression profile of the *Bombyx trh* gene suggests that it may play roles in silk gland and tracheal development that parallel the roles of its *Drosophila* homolog in the salivary gland and trachea. However, as with the *Bombyx fkh* gene, no loss-of-function studies have been done with the *Bombyx trh* gene to confirm a requirement for the gene in forming tubular structures.

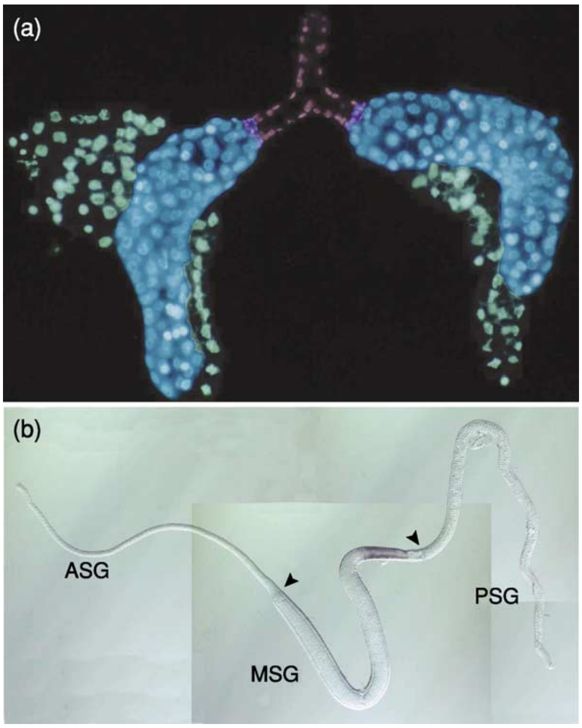

Figure 7 (a) Fluorescent image of a *Drosophila* second instar salivary gland stained with Hoechst and colorized to indicate the different cell types. Salivary secretory cells are shown in cyan, duct cells in pink, and adult precursor imaginal ring cells in purple. The attached fat body cells are shown in green. (Photograph courtesy of A. Haberman.) (b) Phase image of a *Bombyx mori* larval silk gland. The anterior silk gland (ASG) is like the *Drosophila* salivary duct, functioning as a conduit for secretions made in the middle and posterior silk glands (MSG and PSG, respectively). 2.10.5. Salivary Gland Destruction During Metamorphosis

During the normal developmental program of multicellular organisms, programmed cell death allows the removal of unwanted cells in a regulated manner (Raff, 1992). Tissue destruction by programmed cell death is an essential process since, in many tissues, more cells are produced than are necessary or the continued presence of certain cell types may be disadvantageous for the organism. As early as the mid-1930s, larval salivary glands were observed to self-destruct during metamorphosis (Robertson, 1936). In insects and other arthropods, the steroid hormone 20-hydroxyecdysone (20E), induces programmed cell death during larval molting,

resulting in the degradation of the majority of larval tissues (Truman, 1992) (see **Chapters 2.4** and **2.5**). Studies within the past two decades are beginning to reveal the cellular changes associated with salivary gland cell death and to provide a molecular understanding of the genetic regulatory pathway by which stage-specific pulses of 20E lead to programmed cell death. Comparison of cell death in *Drosophila* salivary glands and their structural homologs in other insects suggests a similar 20E-induced mechanism for tissue destruction.

2.10.5.1. Regulation of *Drosophila* Salivary Gland Histolysis

During *Drosophila* metamorphosis, two high-titer pulses of 20E occur, first at the late larval stage and subsequently at the prepupal stage, to signal the end of larval development and the initiation of puparium formation (Riddiford, 1993) (**Figure 8**). In response to 20E, larval tissues, such as the midgut and salivary glands, undergo programmed cell death and are replaced by adult tissues arising from groups of progenitor cells set aside earlier in development. While the larval midgut degenerates in response to the late larval pulse of ecdysone, the larval salivary glands survive the late larval pulse and are only destroyed in response to the prepupal pulse of 20E (Lee *et al*., 2002a). The larval salivary glands are eventually replaced by adult salivary tissue arising from the imaginal ring cells, whereas the larval midgut is replaced by midgut island cells dispersed throughout the larval gut (Robertson, 1936).

Larval salivary glands are destroyed by a cell death pathway that shares features characteristic of both apoptosis and autophagic cell death. Apoptosis is characterized by nuclear and cytoplasmic condensation, DNA fragmentation, and the subsequent clearance of corpses by phagocytes (review: Baehrecke, 2002) and usually occurs at the level of individual dying cells (Kerr *et al*., 1972). In contrast, autophagic cell death occurs by the formation of acidic intracellular vacuoles and subsequent cellular destruction without the aid of nearby phagocytes (review: Baehrecke, 2002). Autophagic cell death is more prevalent in the destruction of parts of or entire tissues (Schweichel and Merker, 1973). Dying salivary gland cells exhibit several characteristics indicative of an autophagic cell death, including large vacuoles containing intracellular structures such as mitochondria (Lane *et al*., 1972; Lee and Baehrecke, 2001) and increases in acid phosphatase activity (Jochova *et al*., 1997). However, salivary gland cell death also involves genes known to function in apoptosis. For example, expression of a caspase gene, *dronc*, increases just prior to salivary gland cell death and the inhibition of caspase activity prevents DNA fragmentation and partially inhibits the cellular changes associated with autophagic cell death (Dorstyn *et al*., 1999; Lee *et al*., 2000; Lee and Baehrecke, 2001). Furthermore, recent genomic approaches to identify genes involved in programmed cell death in the *Drosophila* larval salivary gland confirm and extend the notion that this process in the salivary gland utilizes genes known to be involved in both autophagy and apoptosis (Gorski *et al*., 2003; Lee *et al*., 2003).

Precise regulatory mechanisms are required to ensure that 20E will induce a timely cell death in

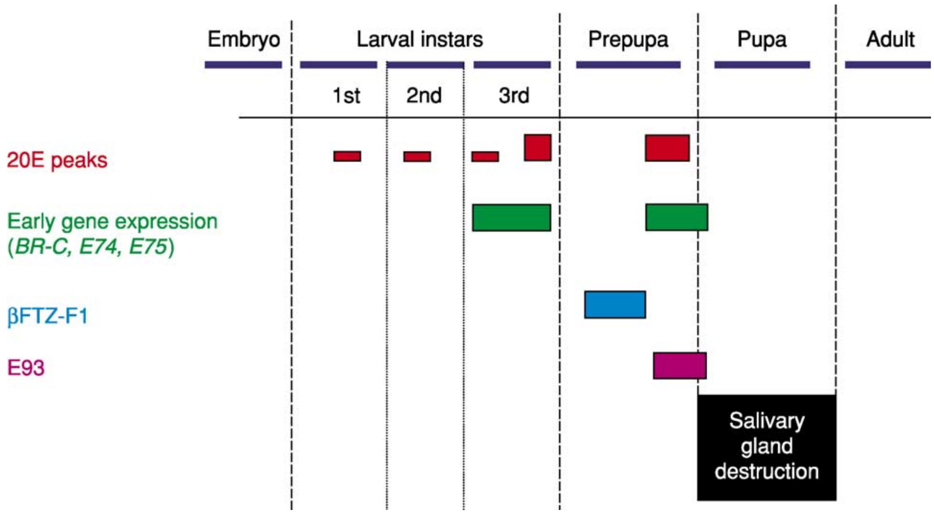

Figure 8 20E-induced gene expression patterns during *Drosophila* metamorphosis. The profile of 20E titer in relation to the expression of the early response genes, BR-C, E74, and E75, the competence factor, βFTZ-F1, and the stage-specific early gene, E93, is shown in correspondence with each of the developmental stages of the *Drosophila* life cycle.

larval tissues while simultaneously promoting development of preadult tissues. To achieve their timely destruction, salivary cells implement a two-step regulatory hierarchy involving the expression of early and late 20E-response genes (**Figure 9**). The 20E receptor is a heterodimer of two nuclear hormone receptors (Thummel, 1995), the ecdysone receptor (EcR) (Koelle *et al.*, 1991) and Ultraspiracle (Usp) (Oro *et al.*, 1990). The existence of additional related orphan receptors, however, raises the possibility that EcR and Usp may also form heterodimers with other receptor-like proteins (Thummel, 1995). The EcR complex promotes salivary gland destruction by directly controlling the expression of a set of early response genes, including the transcription factor genes βFTZ-F1, E74, E75, E93, and the genes in the Broad-Complex (BR-C) (Ashburner, 1974; Richards, 1976). The βFTZ-F1 and E75 genes encode members of the orphan nuclear receptor superfamily (Segraves and Hogness, 1990; Lavorgna *et al.*, 1993), whereas the BR-C genes encode zinc finger transcription factors (DiBello *et al.*, 1991). The E74 gene encodes two isoforms of an ETS-domain transcription factor and E93 encodes a novel nuclear protein (Burtis *et al.*, 1990; Lee *et al.*, 2000). Mutations in each of the early 20E-regulated genes prevents the timely destruction of the larval salivary glands, indicating a role for these genes in salivary gland programmed cell death. For example, mutations in βFTZ-F1 and E93 disrupt the early cellular changes associated with autophagic cell death (Lee *et al.*, 2002b), whereas mutations in the BR-C and E74A genes disrupt cell death progression (Lee and Baehrecke, 2001; Lee *et al.*, 2002b). The 20E-regulated transcription factors activate cell death in the salivary gland by regulating the expression of downstream target genes that are more directly involved in mediating the death response. Downstream targets of the early 20E-regulated genes include the apoptosis inhibitor *diap*; the caspase *dronc*; the caspase-activator *ark*; the apoptosis activators *reaper* (*rpr*) and *head involution defective* (*hid*); and the phagocyte marker *croquemort* (*crq*) (Jiang *et al.*, 1997, 2000; Franc *et al.*, 1999; Kanuka *et al.*, 1999; Lee *et al.*, 2000) (**Figure 9**). Interestingly, *crq* is expressed in the cytoplasm of degenerating salivary cells, suggesting that both phagocytes and autophagic cells may use *crq* for removal of dying cells (Lee and Baehrecke, 2001). The expression of *diap* prior to salivary gland death is activated by βFTZ-F1 and then repressed by E75A and E75B (Jiang *et al.*, 2000). This transient elevation of *diap* expression occurs prior to induction of the apoptosis activators *rpr* and *hid*. Thus, by coordinating the expression of death activators and inhibitors, the 20E-regulated transcription factors βFTZ-F1, BR-C, E74, E75, and E93 are able to precisely control the time of salivary gland destruction.

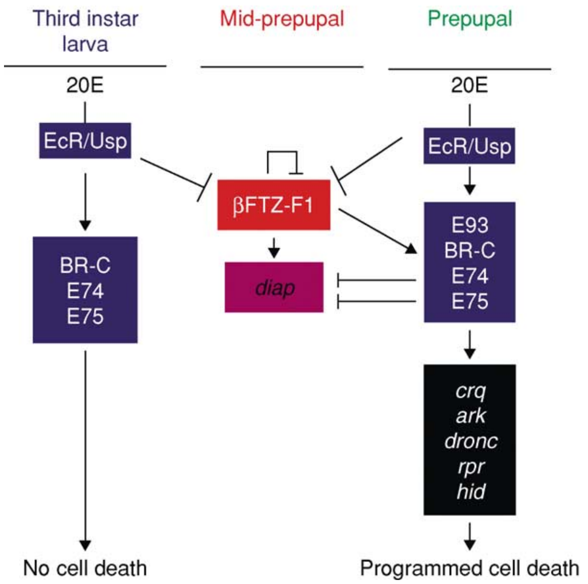

Figure 9 20E-mediated genetic regulatory network leading to salivary gland programmed cell death. At the third instar larval stage, 20E induces transcription of the early response genes, BR-C, E74, and E75, by interacting with the EcR/Usp heterodimer. However, this early induction does not lead to salivary cell death. Low 20E titer at the mid-prepupal stage induces the competence factor, βFTZ-F1, which in turn induces expression of the apoptosis inhibitor, *diap2*, thus delaying programmed cell death until the high titer pulse of ecdysone at the prepupal stage. The βFTZ-F1 protein also facilitates 20E-dependent induction of the early genes, BR-C, E74, and E75, and E93 at the prepupal stage. E93 acts as a stage-specific regulator of cell death by regulating the expression of the early reponse genes as well as the cell death genes, *rpr, hid, ark, dronc*, and *crq*, ultimately leading to programmed cell death in the salivary cells.

The BR-C, E74, and E75 genes are also expressed earlier in the salivary gland and in other tissues without activating PCD. Thus, although these genes are necessary for salivary gland cell death, they are not sufficient. In contrast, the early ecdysone-regulated gene βFTZ-F1 and the stage-specific gene E93, are both necessary and sufficient for inducing salivary gland destruction. Gene βFTZ-F1 transcription is repressed by 20E; its expression is only detected in a brief interval at the mid-prepupal stage when the hormone titers are low (Woodard *et al.*, 1994) (**Figure 8**). The expression of βFTZ-F1 at the mid-prepupal stage reinduces the expression of the late prepupal genes, Br-C, E74A, and E75A, thus acting as a competence factor that allows the expression of these genes in response to the late prepupal pulse of 20E (Lavorgna *et al.*, 1993; Woodard *et al.*, 1994; Broadus *et al.*, 1999) (**Figure 9**). βFTZ-F1

represses its own transcription and as a result ensures a short period of competence (Woodard *et al*., 1994). βFTZ-F1-mediated salivary gland destruction requires the stage-specific early response gene, E93 (Lee *et al*., 2002b). In E93 mutant salivary cells, expression of the 20E-induced early genes, BR-C, E74, and E75, and the cell death genes *rpr*, *hid*, *crq*, and *dronc* are reduced (Lee *et al*., 2000). Like βFTZ-F1, ectopic expression of E93 is sufficient to induce programmed cell death both in tissues that normally undergo hormone-regulated morphogenesis, as well as those that develop in a hormone-independent manner (Lee *et al*., 2000; Lee and Baehrecke, 2001).

Although salivary gland cell death is partly mediated by caspase activity, caspase inhibition by the baculovirus caspase inhibitor, p35, does not inhibit E93-induced cell death (Lee and Baehrecke, 2001). One possible explanation for this disparity is that additional caspase-independent mechanisms may be involved in salivary gland cell death. For example, proteolysis during programmed cell death may involve ubiquitin-mediated destruction in addition to caspases (Schwartz *et al*., 1993; Yang *et al*., 2000). Indeed, in a recent genome-wide analysis of steroid-triggered salivary gland cell death, several noncaspase proteases and related inhibitors have been identified that exhibit dynamic changes in transcription just hours prior to salivary gland destruction (Lee *et al*., 2003).

2.10.5.2. Additional Roles for the BR-C Genes

In addition to the transcriptional regulation of late gene expression during puparium formation (Crossgrove *et al*., 1996), the BR-C proteins are also required earlier at the third larval instar stage for activation of the salivary gland secretion (*Sgs*) genes (Hansson and Lambertsson, 1989). The *Sgs* genes are expressed exclusively in the salivary glands and are required specifically for the production of the glue that allows the puparium to adhere to the substratum (Lehmann, 1995). Activation of the *Sgs* genes requires the BR-C as well as the presence of binding sites for the Fkh transcription factor (Lehmann and Korge, 1996; Mach *et al*., 1996). *In vitro* and *in vivo* studies suggest that Fkh directly controls the salivary gland-specific expression of at least two of the *Sgs* genes, *Sgs-3* and *Sgs-4* (Lehmann and Korge, 1996; Mach *et al*., 1996), and possibly a third, *Sgs-1* (Roth *et al*., 1999). *Sgs* gene expression is subsequently repressed by the *2Bc* function of BR-C in response to the late-larval pulse of 20E (Crowley and Meyerowitz, 1984; Hansson and Lambertsson, 1989); however, *2Bc*-mediated repression of *Sgs* genes is indirect and occurs through Fkh, which is transcriptionally repressed by *2Bc* at puparium formation (Renault *et al*., 2001). Elimination of *fkh* expression by BR-C may also be an early step towards stage-specific destruction of this tissue in response to 20E, since Fkh is essential for salivary secretory cell survival during early embryogenesis. In the absence of *fkh* function, *reaper* and *hid* are transcriptionally upregulated in the embryonic salivary cells, and the salivary gland subsequently degenerates by apoptosis (Myat and Andrew, 2000b). The adult salivary gland will form from the imaginal ring cells that are specified during embryogenesis (Haberman and Andrew, 2003). To date, no studies have been published on the development of the adult salivary gland.

2.10.5.3. Salivary Gland Destruction in Insects other than *Drosophila*

Programmed cell death mediated by 20E in insects other than *Drosophila* also appears to occur by apoptosis and autophagic cell death. The labial glands of the tobacco hornworm, *Manduca sexta*, the anterior silk gland of the silkworm *B. mori*, and the salivary glands of the blowfly *Calliphora vomitoria*, all undergo programmed cell death in response to ecdysone. Programmed cell death during larval–pupal metamorphosis in the *Manduca* labial glands is characterized by the intracellular movement of lysosomes and fragmentation of the endoplasmic reticulum, resulting in the formation of large intracellular vacuoles (Halaby *et al*., 1994). Massive vacuolization of the cell occurs concomitantly with large-scale DNA damage and fragmentation (Jochova *et al*., 1997). These characteristics of labial gland destruction in *Manduca* suggest an autophagic as well as an apoptotic type of cell death, as occurs in the salivary glands of *Drosophila* early pupae.

In the silkworm *B. mori*, ecdysone induces programmed cell death of the anterior segment of the silk gland during the larval–pupal transition (Chinzei, 1975; Terashima *et al*., 2000). Morphological and biochemical studies of silk gland destruction demonstrate the increased presence of autophagosomes and the prevalent role that lysosomes play in the degradation of cytoplasmic organelles (Shiba *et al*., 2001). Furthermore, programmed cell death of the *Bombyx* silk gland occurs in the absence of phagocytes, as observed in the *Drosophila* salivary gland (Matsura *et al*., 1968). In a recent study, the cathepsin B- and L-like lysosomal proteinases were found to be involved in the destruction of the silk gland (Shiba *et al*., 2001). In addition to lysosomal proteinases, the ubiquitin–proteasome system may also be involved in the removal of

cytoplasmic proteins during programmed cell death in the silk gland (Ichimura *et al*., 1994).

While DNA fragmentation is often described as a hallmark of apoptotic cell death and is prevalent during *Drosophila* salivary gland degeneration (Lee and Baehrecke, 2001), studies in *Manduca* and *Calliphora* suggest that DNA fragmentation may not contribute to cell death to the same extent as it does in mammalian cells. In programmed cell death of the *Manduca* labial gland, vacuolization and cytoplasmic destruction are prominent very early, with DNA fragmentation only occurring at the end of gland destruction (Zakeri *et al*., 1993). Similarly, in the dying cells of the *Bombyx* silk gland, the degree of nuclear condensation and DNA fragmentation is variable (Terashima *et al*., 2000).

Finally, salivary gland cell death in *Calliphora* also occurs by vacuolization of the cell and the subsequent dispersal of cellular contents into the lumen; however, no evidence exists to date for a role for DNA degeneration during gland destruction (Bowen *et al*., 1993). Thus, 20E-induced glandular destruction in the insects described above appears to always include early vacuole-mediated cytoplasmic destruction, whereas the involvement of nuclear DNA fragmentation varies.

2.10.6. Salivary Gland Physiology and Disease

For blood-feeding arthropods, such as the mosquito *Anopheles* and the Ixodidae family of hard ticks, the salivary glands are essential for feeding and serve additional functions. In both mosquitoes and ticks, sexual dimorphism exists for feeding habits and correlates with salivary gland morphology. In mosquitoes, although both sexes feed on sugar solutions of fruits and flora, only the female takes blood meals. The mosquito salivary gland is a simple, relatively unbranched tubular structure comprising two lateral lobes and a single medial lobe; the female salivary gland is larger and is composed of more cell types than its male counterpart (James, 1994). Similarly, female ixodid ticks consume large quantities of blood over an extended period of time, whereas male ticks feed only occasionally and on low volumes of blood.

Ixodid tick salivary glands consist of two large lateral glands with multiple branches containing both ducts and *acini* (*alveoli*). A single large duct within each of the two glands allows access to the food channel through a broad, shallow tube called the *salivarium* (review: Sauer *et al*., 1995). Female ixodid ticks have three types of *alveoli* whereas male ticks have four, with each *alveolus* differing in morphology and in the type and number of granular and agranular cells it contains (Sauer *et al*., 1995). In newly hatched ixodid larvae, the salivary glands are extremely small and only ducts are distinguishable. At later larval stages, three types of *alveoli* are observed.

Salivary gland destruction in ixodid ticks occurs after larvae become engorged from blood feeding and is characterized by degeneration of only the *alveoli* (Sauer *et al*., 1995). The remaining salivary ducts form branching structures with small terminal *alveoli* containing undifferentiated cells. The undifferentiated *alveoli* increase in number and subsequently differentiate into the three or four types of *alveoli*, depending on gender (Sauer *et al*., 1995). During metamorphosis to adult, the salivary glands degenerate and redifferentiate through a process similar to that occurring in the larval glands (Sauer *et al*., 1995). As with the other insects described here, salivary gland degeneration in ixodid ticks is also thought to be triggered by 20E (Harris and Kaufmann, 1985).

The ixodid tick salivary gland is a multifunctional organ that secretes a cement substance, which allows the slow-feeding ticks to attach firmly to the host. The gland also secretes toxic substances and pharmacological agents that cause tissue destruction at the site of feeding, ultimately leading to trauma to the host (review: Sauer, 1977). Salivary glands of ixodid ticks also serve as osmoregulatory organs. During the off-host stage when the tick is not feeding, which comprises the majority of its life cycle, the salivary glands secrete a hygroscopic solution onto the mouthparts, which absorbs water from unsaturated air and allows the tick to remain hydrated (Sauer *et al*., 1995). In contrast, during feeding and attachment to the host, the tick concentrates the blood meal and eliminates excess fluid and ions by secreting them back into the host through the salivary glands (Sauer *et al*., 1995). Approximately one third to one half of the ingested fluid is secreted back to the host using this mechanism.

Blood-feeding arthropods serve as important vectors for diseases caused by such pathogens as viruses, bacteria, rickettsiae, and protozoa. The most common route of infection is through the salivary glands with certain pathogens replicating within the salivary cells (review: Bowman *et al*., 1997). Plasmodium parasites, which cause malaria, are transmitted by the blood-sucking mosquito, *Anopheles gambiae*. During the parasite's life cycle in the *Anopheles* vector, sporozoites invade the salivary gland epithelium by attaching to the basal lamina (Pimenta *et al*., 1994). After a transient stay in the cytoplasm, the sporozoites enter the secretory cavity

where they remain viable for the life of the mosquito (review: Ghosh *et al*., 2000). During blood feeding, a small number of sporozoites enter the vertebrate host through the salivary duct. Saliva not only serves to deliver the sporozoites but also aids in their infectivity since it contains pharmacologically active compounds capable of counteracting the host's defense mechanisms (Ghosh *et al*., 2000). Inhibition of salivary gland invasion by *Plasmodium* sporozoites may be one approach towards elimination of malaria.

2.10.7. Conclusion

Recent studies of the *Drosophila* salivary glands have revealed many of the underlying mechanisms and molecules required to form an organ and to mediate its destruction at appropriate developmental stages. Such studies provide meaningful paradigms for organ specification, formation, and homeostasis in higher organisms, including humans. Recent studies in other insect species suggest a high level of conservation of regulatory molecules controlling both the genesis and demise of salivary gland cells. This high level conservation of gene function may ultimately yield strategies for limiting the spread of the many pernicious human and animal diseases carried by insect vectors.

Acknowledgments

The authors thank the many people whose work has contributed to their understanding of insect salivary gland development, physiology, and destruction, E. Baehrecke and A. Haberman for their critical reading of the chapter, S. Karim for sharing the tick and mosquito salivary gland literature, and A. Haberman for the image of the second instar *Drosophila* salivary gland and Y. Suzuki for the image of the *B. mori* silk gland. Their current research on *Drosophila* salivary gland development is supported by NIH RO1 DE12873 and RO1 DE13899 grants (to D.J.A.), and an NIH K22 Award (to M.M.M.).

Appendix Genes involved in salivary gland specification, morphogenesis, and programmed death

Gene	*Protein*	*Role in salivary gland*
Abdominal-B (Abd-B) (see **Chapter 1.8**)	Homeodomain transcription factor expressed in posterior abdominal segments	Blocks salivary gland formation in PS14
Apaf-1-related-killer (Ark)	Caspase activator	Role in programmed larval salivary cell death during metamorphosis
βFTZ-F1	Ligand-dependent nuclear receptor transcription factor	Regulation of programmed larval salivary cell death during metamorphosis
breathless (btl)	Transmembrane receptor tyrosine kinase (FGF receptor) expressed in duct cells under control of TRH	Role in duct unknown, no visible defects in mutants
brinker	Nuclear transcription factor	Blocks transcription of Dpp target genes, mutations result in smaller salivary glands
Broad-Complex (BR-C)	BTB/POZ ranscription factors induced early and late in response to ecdysone signaling	Regulation of programmed larval salivary cell death during metamorphosis
croquemort (crq)	Plasma membrane protein; scavenger/ macrophage receptor	Role in programmed larval salivary cell death during metamorphosis
crumbs (crb)	Transmembrane protein localized to apical membranes and subapical region of epithelial cells	Specification and maintenance of apical membrane domains of salivary epithelial cells
decapentaplegic (dpp)	Secreted protein of the TGF-β family expressed in dorsal cells	Represses salivary gland formation in dorsal cells of PS2
dead ringer (dri)	ARID-box transcription factor expressed in duct cells, repressed in secretory cells by Fkh	Role in duct unknown, no visible defects in mutants
dorsal (dl)	Transcription factor with nuclear localization in ventral cells	Specification of ventral cell fates; mutants do not have salivary glands
dronc	Nedd2-like caspase	Salivary gland destruction during metamorphosis
Drosophila inhibitor of apoptosis (diap)	Inhibitor of apoptosis	Regulation of programmed larval salivary cell death during metamorphosis
E74	Transcription factor induced early and late in response to ecdysone signaling	Regulation of programmed larval salivary cell death during metamorphosis
E75	Ligand-dependent nuclear receptor transcription factor	Regulation of programmed larval salivary cell death during metamorphosis
E93	Transcription factor induced late in response to ecdysone signaling	Regulation of programmed larval salivary cell death during metamorphosis

Continued

Appendix Continued

Gene	Protein	Role in salivary gland
Ecdysone receptor (EcR)	Receptor subunit for steroid hormone 20-hydroxyecdysone	Regulation of programmed larval salivary cell death during metamorphosis
epidermal growth factor receptor (EGF-R)	Transmembrane receptor tyrosine kinase (EGF receptor)	Blocks salivary gland secretory cell fate, allowing salivary gland duct cell fate
extradenticle (exd)	Homeodomain transcription factor expressed relatively ubiquitously	Salivary gland specification
eyegone (eyg)	PAX family transcription factor expressed dynamically in subset of secretory and duct cell primordia	Individual duct specification, potential role in specification of imaginal ring cell fate
fork head (fkh)	Winged-helix transcription factor expressed in the secretory cells	Secretory cell internalization, prevention of apoptotic cell death, repression of duct gene expression in secretory cells, activation of glue gene expression in late larval glands
hairy (h)	Myc-like bHLH transcription factor expressed transiently in secretory cells	Prevention of branching and bulging by limiting apical membrane growth in secretory cells through transcriptional repression of *hkb* and *klar*
head involution defective (hid)	Inducer of programmed cell death	Positive activator of programmed cell death (autophagy) in larval salivary glands during metamorphosis
heart broken (hbr)	Cytoplasmic protein required for FGF signaling	Mesodermal migration, required to form intact visceral mesoderm for salivary gland posterior migration
heartless (htl)	Transmembrane receptor tyrosine kinase (FGF receptor)	Mesodermal migration, required to form intact visceral mesoderm for salivary gland posterior migration
homothorax (hth) (see **Chapter 1.8**)	Homeodomain transcription factor expressed relatively ubiquitously	Salivary gland specification
huckebein (hkb)	Zinc finger transcription factor expressed transiently and dynamically in early secretory cells	Apical membrane growth and tube elongation in secretory cells through transcriptional activation of *crb* and *klar*
inflated (if)	PS2 α-integrin subunit; transmembrane protein (expressed in mesoderm)	Migration of secretory cells
klarsicht (klar)	Cytoplasmic protein proposed to mediate minus-end transport of organelles along microtubules	Apical membrane growth/delivery in secretory cells
Multiple edematous wings (mew)	PS1 α-integrin subunit; transmembrane receptor (expressed in secretory cells)	Migration of secretory cells
Notch (N)	Transmembrane receptor; upon signaling, C-terminal fragment enters nucleus to regulate transcription	Prevents neurogenic fate in salivary gland precursors; later, specification of imaginal ring cells
reaper (rpr)	Cytoplasmic inducer of programmed cell death	Positive activator of programmed cell death (autophagy) in larval salivary glands during metamorphosis
rhomboid (rho)	ER localized transmembrane protease required for processing of EGF ligands, expressed in ventral cells	Blocks salivary gland secretory cell fate, allowing salivary gland duct cell fate
ribbon (rib)	Putative transcription factor with BTB/POZ domain and domain of homology to Pipsqueak DNA-binding domains	Migration of secretory cells, elongation of duct tubes
scabrous (sca)	PS3 α-integrin subunit; transmembrane receptor (expressed in secretory cells)	Mild defects in salivary gland placement at late stages
Serrate (Ser)	Transmembrane ligand for Notch, expressed in duct cells, repressed in secretory cells by Fkh	Specification of imaginal ring cell fate in salivary cells neighboring the duct precursors, required for actin-ring structures in duct
Sex combs reduced (Scr) (see **Chapter 1.8**)	Homeodomain transcription factor expressed in parasegment 2 (PS2)	Salivary gland specification
spitz (spi)	Secreted EGF ligand	Blocks salivary gland secretory cell fate, allowing salivary gland duct cell fate
teashirt (tsh)	Zinc finger transcription factor expressed in trunk and abdominal segments	Blocks salivary gland formation in PS3–13
tetraspanin 74F (tsp74F)	Transmembrane protein expressed in imaginal ring cells during embryogenesis	Function in imaginal ring cells unknown

Continued

Appendix Continued

Gene	*Protein*	*Role in salivary gland*
thick veins (tkv)	Transmembrane serine/threonine kinase, Dpp receptor	Represses salivary gland formation in dorsal cells of PS2
tinman (tin)	Homeodomain-containing nuclear transcription factor	Specification of visceral mesoderm precursors; required to form intact visceral mesoderm for salivary gland posterior migration
trachealess (trh)	bHLH-PAS transcription factor expressed transiently in all salivary cells, later restricted to duct cells by Fkh repression	Internalization of duct precursors to form the salivary duct tubes
twin of eyegone (toe)	PAX family transcription factor expressed dynamically in subset of secretory and duct cell primordia	With *eyegone* may have a role in individual duct specification and a potential role in specification of imaginal ring cell fate
Ultraspiracle (Usp)	Receptor subunit for steroid hormone 20-hydroxyecdysone	Regulation of programmed larval salivary cell death during metamorphosis

2.11 Silk Gland Development and Regulation of Silk Protein Genes

E Julien, M Coulon-Bublex, and A Garel,
CNRS-Université Claude Bernard, Lyon, France
C Royer and G Chavancy, INRA, Unité Nationale Séricicole, La Mulatière, France
J-C Prudhomme and P Couble, CNRS-Université Claude Bernard, Lyon, France

2.11.1. Introduction

With its many inherent merits, the silkworm *Bombyx mori* has been established as a domesticated insect exploited for sericulture and as a model system for basic research. The growing collection of the silkworm genetic stock worldwide – some 3000 genotypes – places *B. mori* second to *Drosophila* for genetic studies in insects (Nagaraju *et al.*, 2001). Amongst the biological processes investigated in *B. mori*, the study of the differentiation of the silk gland, the organ that synthesizes, secretes, and organizes the silk proteins into a thread, has attracted constant attention. The silk gland is very simply organized as a one-cell layered glandular epithelium that comprises two distinct types of secretory cells, the one that produces fibroin and the other that synthetizes sericins, the two components of silk. The high specialization of these cells provides an excellent opportunity to study the repertoire of regulatory factors that specify each of them.

Investigations on the regulation of silk protein genes have identified a series of transcription factors, which may also play key functions in the development of the silk gland. They have, moreover, suggested that chromatin-remodeling activities are very important in modifying the accessibility of the transcription factors to their target DNA sequences in the two categories of secretory cells. Thus, both qualitative and quantitative differences in regulatory gene expression probably induce the selective activation of the promoters of the different silk-encoding genes in the two categories of cells. One challenging problem that remains is to understand how these transcriptional differences are achieved during the course of development of the silk gland and how they are maintained during the impressive postembryonic growth of the organ. This review aims at summarizing our current knowledge on the development of the silk gland and the mode of production of silk proteins.

2.11.2. The Functioning of the Silk Gland

2.11.2.1. The Silk Gland Epithelium

The silk gland of *B. mori* is a tubular epithelium divided in three regions with precise cell-to-cell boundaries and a fixed number of cells (Figure 1). The posterior (PSG) and the middle (MSG) silk gland are secretory territories specialized for the massive production of the silk proteins. The three fibroin subunits, encoded by the heavy fibroin chain (*h-fib*), light fibroin (*l-fib*), and fibrohexamerin (*fhx*) (formerly referred to as *P25*) genes, are synthesized in the PSG cells whereas the sericins encoded

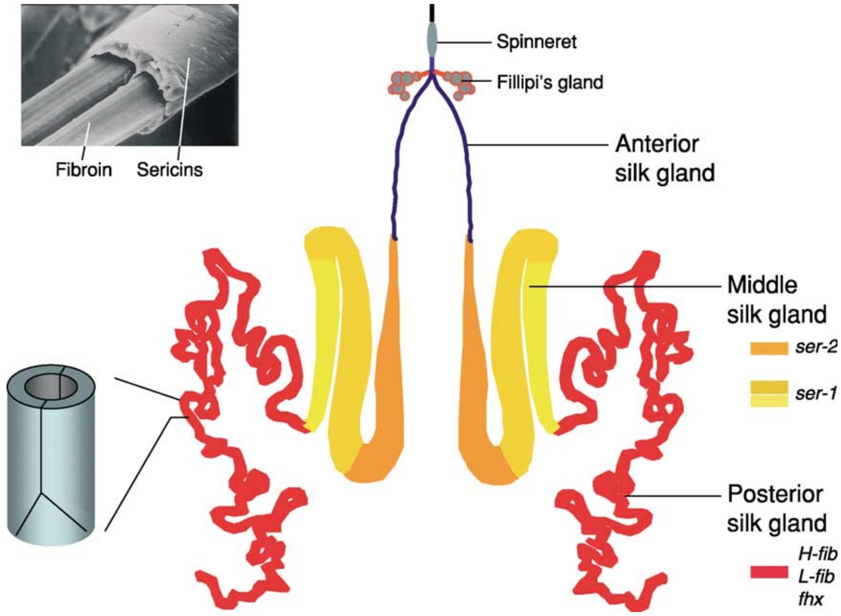

Figure 1 *Bombyx mori* silk gland organization. The silk protein encoding genes expressed in the different territories of the gland are shown by colors. The two middle silk gland (MSG) territories expressing *ser-1* correspond to two subpopulations of cells exerting distinct splicing modalities of the *ser-1* mRNA precursor (see Section 2.11.2.3). In the most anterior section, the paired ducts, to which the Fillipi's glands abduct, fuse into a single narrow canal at a short distance from the spinneret. The left-hand side shows the organization of the secretory epithelium with one layer of silk protein secreting cells surrounding a lumen and two cells facing each other. The upper left insert shows a scanning microscope picture of the two cables of insoluble fibroin spun out the right and left silk glands embedded in a matrix made of sericins. (Courtesy of Giuliano Freddi.)

by the genes *ser-1* and *ser-2* are produced in the MSG cells (Maekawa and Suzuki, 1980; Couble *et al.*, 1985, 1987; Kimura *et al.*, 1985; Horard *et al.*, 1997). Paired secretory parts are linked to the labial spinneret by long fine ducts, the anterior silk glands (ASG), to which the glands of Fillipi adduct and discharge their secretion (**Figure 1**).

Silk gland morphogenesis is completed in the embryo 24–48 h before hatching. Full differentiation is characterized by the transcription of all five silk protein-encoding genes in the embryo silk gland, and the synthesis of silk that is spun out by the newly hatched larvae (Maekawa and Suzuki, 1980; Ohta *et al.*, 1988; Matsunami *et al.*, 1998). Following differentiation, the growth of the silk gland is rhythmically controlled by the regular occurrence of endomitotic cycles during each of the five larval instars. The succession of 18 replication cycles in most of the PSG cells results in the presence of an estimated 400 000 haploid genomes per PSG cell at the end of the larval life. An additional replication cycle takes place in most of the MSG cells leading to twice the nuclear amount of DNA than observed in PSG cells (Perdrix-Gillot, 1979). The massive amplification of DNA by endomitotic cycles preserves the representation of each individual chromosome and locus (Gage and Manning, 1976).

The specializations of PSG and MSG cells remain unchanged during the spectacular growth of the organ suggesting that the relevant "guiding" information is restored after each round of DNA replication, likely through mechanisms that duplicate and maintain precisely the ordered structure of chromatin. Even though the ploidy level of fully grown silk gland cells is the highest ever reported for eukaryotic cells, silk gland development is reminiscent of many other insect tissues, whose growth is similarly associated with endomitoses.

The fifth and last intermolt is featured by a hypertrophy of the silk gland and by an increased rate of silk protein synthesis, prior to cocoon spinning, with associated cell ultrastructural changes related to the massive protein synthesis, transport, and secretion. After cocoon spinning, the silk gland initiates an apoptotic process that leads to its complete degeneration. This cell death program, mostly studied in the anterior silk gland, is likely under the action of 20-hydroxyecdysone (20E) and the BmEcR-A and -B1 isoforms of its receptor (Chinzei, 1975; Kamimura *et al.*, 1997; Terashima *et al.*, 2000).

Silk is mainly composed of fibroin and sericins, whose genes have been cloned and their transcriptional regulation studied, as described below. It also contains minor polypeptides referred to as seroins,

which do not contribute to the silk thread structure. Potent proteinase inhibitors are also present and it is speculated that their activity confers protection to the cocoon against proteolysis by microbe proteases (Grzelak *et al.*, 1988; Zurovec *et al.*, 1998b; Nirmala *et al.*, 2001; review: Fedic *et al.*, 2002). No investigation of the regulation of expression of seroin and proteinase inhibitor genes is yet available.

2.11.2.2. The Posterior Silk Gland Cells and Fibroin Production

PSG cells produce fibroin, the matter of the insoluble core of the silk thread. This complex protein is composed of three subunits: the heavy (H-fibroin) and the light fibroin chain (L-fibroin) which are linked through disulfide bonds, and fibrohexamerin (previously designated P25), which is associated with the H-fibroin/L-fibroin dimer through noncovalent bonds (Inoue *et al.*, 2000). The stoichiometry relationship accommodates a 6 : 6 : 1 relative ratio of the three subunits, as shown on the schematic representation of fibroin presented in **Figure 2**.

The 391 kDa H-fibroin subunit confers the remarkable physicochemical properties to the silk fiber. It is encoded by a 17 kb long gene, organized in one short and one very long exon separated by a 1 kb intron (Tsujimoto and Suzuki, 1979). The *h-fib* gene is located at one extremity of linkage group 25 (Doira, 1983). The complete sequencing of the gene (together with 60 kbp of the 5′ flanking domain) allowed the deduction of the sequence of the entire protein (Zhou *et al.*, 2000). H-fibroin is a 5263-residue polypeptide chain with high glycine content (46%) that exhibits a characteristic structure with 12 crystalline domains made of Gly-X repeats alternating with 11 identical 43-residue spacer sequences. The repetitive domains fold in canonical β-pleated sheet structures, and build up the protein crystal moiety of the silk thread. The 151 and 58 residues at the N- and C-termini are nonrepetitive. The C-terminal sequence carries three cysteine residues, the first one being implicated in a disulfide bond to L-fibroin, whereas the two others form an intramolecular bond (Tanaka *et al.*, 1999b) (**Figure 2**).

The *l-fib* gene is 13.5 kb long. It encompasses seven exons and maps onto linkage group 14 (Hyodo *et al.*, 1984; Kimura *et al.*, 1985). The very large first intron, which accounts for about 60% of the gene, contains multiple repeated sequences, some of them related to the *Bm1* and *BmX* transposable elements (Kikuchi *et al.*, 1992). The *l-fib* gene codes for a 25.8 kDa protein characterized by a relatively high incidence of leucine, isoleucine, valine, and acidic amino acids. It is linked to H-fibroin through a single disulfide bond that mobilizes cysteine 172, the two other cysteine residues forming an intra-chain bond (Tanaka *et al.*, 1999b) (**Figure 2**).

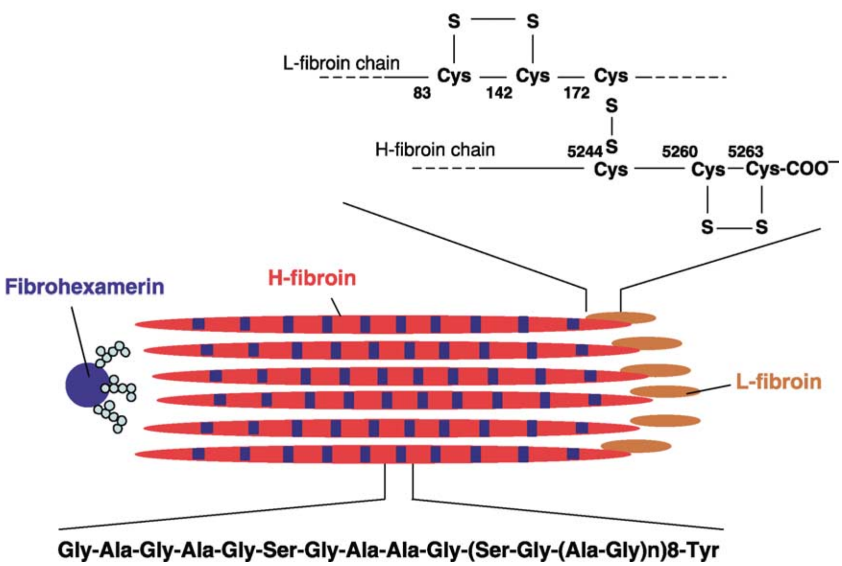

Figure 2 Molecular organization of fibroin. Schematic representation of the supramolecular organization of fibroin, the insoluble component of silk. The spatial arrangement of the six H-fibroin–L-fibroin dimers bond to one fibrohexamerin molecule is hypothetical and inferred from the data of Tanaka *et al.* (1999a, 1999b) and Inoue *et al.* (2000). H-fibroin is symbolized as a linear chain with the succession of 12 highly repeated regions (characterized by a typical glycine-rich motif) and the alternation of spacer sequences. The intra- and intermolecular disulfide bonds in the L-fibroin chain and in the C-terminus of the H-fibroin chain are shown in the upper portion of the figure. Fibrohexamerin hydrophobic interactions with H-fibroin is represented arbitrarily at the N-terminal region of the H-fibroin chains. Fibrohexamerin is displayed with its three *N*-linked oligosaccharide chains.

The L-chain and H-chain covalent bond is essential for the intracellular transport and secretion of the fibroin complex (Takei *et al.*, 1987). This was demonstrated by studying two *l-fib* mutant alleles (*Nd-s* and *Nd-s*^{D}) that display a “naked pupa” phenotype, where pupae are covered with a very thin and transparent cocoon. *Nd-s* mutants secrete only 0.3% of the normal-level fibroin producers and their silk consists mostly of sericins. In both the *Nd-s* and *Nd-s*^{D} strains, the L-fibroin and H-fibroin covalent linkage is impaired and the heavy chain is retained in the endoplasmic reticulum (Mori *et al.*, 1995); correlatively, the Golgi apparatus and fibroin secretory vesicles are poorly developed (Gamo and Sato, 1985). It is likely that the covalent bonding between H-fibroin and L-fibroin chains is required to free the membrane-anchored H-chain and allow its translocation to the Golgi vesicles. The blocking of fibroin secretion is accompanied by a severe reduction in the growth of the PSG, whereas the MSG develops normally (Takei *et al.*, 1987). This remarkable pleiotropic effect of the Nd-s and Nd-s^D mutations suggests a feed back between silk secretion and cell growth.

Fibrohexamerin is a 220 amino acid long peptide encoded by *fhx*, a 3.5 kb single-copy gene with five exons (Couble *et al.*, 1985; Chevillard *et al.*, 1986). It is linked to the H-fibroin–L-fibroin dimer through hydrophobic interactions with H-fibroin (Tanaka and Mizuno, 2001). Its function is viewed as an organizer of a supramolecular unit combining six H-fibroin–L-fibroin dimers and one molecule of fibrohexamerin. This would allow transport of the complex into the organelles and secretion of the H-fibroin chain into the gland lumen in a soluble conformation (Inoue *et al.*, 2000). *N*-linked oligosaccharides anchored at three asparagine residues of fibrohexamerin are likely to play a critical role in the interactions with H-fibroin (Tanaka *et al.*, 1999a). This role is probably ancestral, since a fibrohexamerin ortholog was identified in several lepidopteran species such as *Galleria mellonella* (Zurovec *et al.*, 1998a), *B. mandarina*, *Dendrolimus spectabilis,* and *Papilio xuthus* (Tanaka and Mizuno, 2001). By contrast, the moths of the Saturnidae secrete a fibroin molecule made by the dimerization of a H-fibroin-like protein and are apparently devoid of *l-fib* and *fhx*-like genes (Tanaka and Mizuno, 2001).

2.11.2.3. The Middle Silk Gland Cells and Sericin Production

The sericin fraction of the silk is composed of related peptides produced in MSG cells and characterized by their solubility in hot and alkaline water, a property that enables the industrial degumming of silk, and by their unusual composition, in which serine represents about one-third of all amino acids (Lucas and Rudall, 1968). Sericins serve to glue the silk threads together. Their diversity arises from frequent allelic polymorphisms of the two single-copy genes, *ser-1* and *ser-2*, and from the differential splicing of their respective precursor mRNA (Okamoto *et al.*, 1982; Michaille *et al.*, 1986, 1990a; Garel *et al.*, 1997).

The *ser-1* gene, which encodes the four major sericins of the silk thread, maps genetically on the *src-1* locus in linkage group 11 (Gamo, 1982). It is a 23 kb long gene with nine exons, from which four mature mRNA species are expressed, 10.5, 9.0, 4.0, and 2.8 kb long (Michaille *et al.*, 1986). The larger exon that spreads over 6 kb carries tandem arrays of a 114 bp sequence encoding a 38-residue long serine-rich motif.

The 12-kbp *ser-2* gene that contains four exons (Michaille *et al.*, 1990a, 1990b) is likely located at the *Src-2* locus in the same linkage group as *Src-1* (Gamo, 1982). Differential splicing of its pre-mRNA gives rise to two mature transcripts of 3.1 kb for one, and 5–6.4 kb, depending on the *ser-2* allele, for the other. Size variations are attributed to the occurrence of unequal crossovers within a region carrying multiple well-conserved 45 bp repeats.

The expression of *ser-1* and *ser-2* is not synchronous and varies both temporally and spatially during the last larval instar. Indeed, the MSG cells expressing *ser-1* are specialized for the synthesis of distinct mature mRNAs, depending on their topological location and on the stage of development (Michaille *et al.*, 1986; Couble *et al.*, 1987). The territory of expression of *ser-1* comprises the 150 most posterior MSG cells, contiguous to the PSG (**Figure 1**). This territory includes two subpopulations of cells: the 42 most posterior ones which are specialized in the expression of the shortest 2.8 kb *ser-1* mRNA during the whole instar, and the 108 more anterior ones (**Figure 1**) which realize the three other modalities of splicing in a sequential manner, leading to the successive accumulation of the 4.0, the 10.5, and the 9.0 kb mRNAs. In these last cells, the modalities of splicing of the *ser-1* primary transcript change twice during the last instar. The mechanisms that trigger these changes have not been deciphered, nor is it fully understood whether they relate to the two rounds of endoreplication that take place in MSG cells during the same period.

The expression of the other sericin gene, *ser-2*, is featured by the coaccumulation of the two corresponding mature mRNAs in about the same

proportion. In the early stages of the fifth larval instar, all MSG cells express *ser-2*, but the synthesis of the two mRNAs is progressively restricted to the 120 most anterior cells of the middle silk gland, which do not express *ser-1* (Couble *et al.*, 1987) (Figure 1).

The finely tuned regulation of expression of *ser-1* and *ser-2* leads to a characteristic deposition of the different sericins onto the fibroin stored in the lumen of the middle silk gland (Couble *et al.*, 1987), and likely provides a peculiar organization of the compacted silk proteins prior to spinning. A similar regulation of alternative splicing of the primary transcript of the two sericin genes was also observed in *G. mellonella* (Fedic *et al.*, 2002), suggesting that it may represent a common mechanism that contributes to the generation of diversity of sericins in the Lepidoptera.

2.11.3. Transcriptional Regulation of Silk Protein Genes

Many direct and indirect observations support the notion that transcription is the main step at which the expression of the five silk protein encoding genes, *h-fib*, *l-fib*, *fhx*, *ser-1*, and *ser-2* is controlled (Tsujimoto and Suzuki, 1979; Maekawa and Suzuki, 1980; Couble *et al.*, 1983; Couble *et al.*, 1985; Kimura *et al.*, 1985; Michaille *et al.*, 1989). As reviewed below, original experimental strategies, mostly dedicated to *h-fib, ser-1*, and *fhx*, were developed to identify the factors involved in PSG- and MSG-specific expression (Table 1). Efforts were made subsequently to progress on the central issue of chromatin organization and the control of access of the *trans*-regulatory factors to their target sequences.

2.11.3.1. Regulation of *h-fib*: Are Homeoproteins Involved?

Cell-free transcription assays employing silk gland nuclear extracts were used by Suzuki and coworkers to reproduce the PSG and MSG cell specificities of expression (Suzuki *et al.*, 1986; Matsuno *et al.*, 1989). Sequences immediately upstream of *h-fib*, located at −167 to −115 and at −73 to −44, were first shown to be capable of enhancing *in vitro* transcription. The enhancer effect was dependent upon silk gland-specific *trans*-acting factors, since it was observed only with PSG or MSG extracts but not with other systems derived from *B. mori* cultured cells or ovaries, *Antheraea* silk glands, or HeLa cells (Hirose *et al.*, 1985). Besides the enhancer sequences, a contribution of both the transcription initiation region around the TATA box and an intronic sequence in the regulation of the gene was also suggested (Takiya *et al.*, 1990; Takiya and Suzuki, 1993). The opposing transcriptional status of *h-fib* in PSG and MSG cells (where it is expressed and permanently repressed, respectively) could not, however, be reconstituted *in vitro*, despite many

Table 1 Characteristics of the trans-regulatory factors acting *in vitro* or *in vivo* on the different silk protein gene promoters in the posterior and the middle silk gland cells

Factors	*Gene promoter*	*Tissue incidence*	*Comments*	*Reference*
BmFA	*fhx*	Ubiquitous	Posttranslationally modified at the onset of each larval molt correlatively to *fhx* repression	Durand *et al.* (1992) Nony *et al.* (1995)
BmFKH (FMBP-2 or SGF-1 or SGFB)	*fhx h-fib ser-1*	MSG and PSG cells	*In vitro* (*ser-1* and *h-fib*) and *in vivo* (*fhx*) powerful activator; homologous to the *Drosophila* forkhead protein	Mach *et al.* (1995) Horard *et al.* (1997) Julien *et al.* (2002) Takiya *et al.* (1997)
FF1	*h-fib*	Ubiquitous	A 125 kDa putative activator that binds DNA *in vitro* with another factor FF2 to *h-fib* elements	Hui *et al.* (1990)
FMBP-1	*h-fib*	Abundant in PSG at feeding stages, and in ovarian tissues	Binds *in vitro* the upstream and intronic modulators of *h-fib.*	Takiya *et al.* (1997)
POU (Pit1/Oct-1/Unc-86)-M1 (FMBP-3 or SGF-3)	*h-fib ser-1*	Ubiquitous, but abundant in MSG cells	38 kDa factor of the POU type family of factor; possible *ser-1* activator (see Section 2.11.3.2). Binds *in vitro* to *h-fib* upstream and intron elements.	Fukuta *et al.* (1993) Takiya *et al.* (1997)
SGF-4	*h-fib ser-1*	Ubiquitous	Binds *in vitro* to homeodomain protein consensus sequences of the *h-fib* promoter	Hui *et al.* (1990)

refinements in the protocol and the use of fractionated PSG and MSG extracts (Suzuki *et al.*, 1990).

In vitro DNA-protein interactions using probes taken in the *h-fib* upstream domain (−214 to −66) and in the intron, led to the identification of putative regulatory factors, all featuring the capacity to bind very AT-rich sequence elements (Takiya *et al.*, 1990, 1997) (**Table 1**). A series of *in vitro* DNA–protein complexes were observed, among which SGF-1 (further named as BmFKH) was the first to be found to be specific for silk gland cells and to be present in both the PSG and the MSG (Suzuki and Suzuki, 1988; Hui *et al.*, 1990). The target sequences to which these complexes bind, contain frequent TTAATT or AATTAA motifs (see **Chapter 1.8**), like the core element of homeodomain binding sites, and it was hypothesized that proteins encoded by homeogenes likely activate *h-fib* (Hui and Suzuki, 1990, 1995). The observation that the *Drosophila* homeoproteins EVE and ZEN could bind *in vitro* at these same sites supported this hypothesis (Hui *et al.*, 1990), which, however, still awaits *in vivo* validation.

These studies suggested that *h-fib* expression is controlled by ubiquitous and silk gland-specific factors, that likely define both the tissue specificity and the intensity of transcription. However, they did not provide any specific explanations for the PSG restricted expression of *h-fib*. Thus, the question is still open as to whether this property simply rests upon the existence of PSG-specific factors or combination of factors, or from a specific structure of the gene in PSG cell chromatin, that is maintained by nonspecific chromatin remodeling proteins throughout larval development.

A study of the distribution of DNaseI hypersensitive sites within a 46 kb genomic region encompassing *h-fib* revealed the existence of several PSG-specific hypersensitive sites at 2 kbp and as far as 17 and 20 kbp upstream from the transcription start site (Waga and Mizuno, 1993). Interestingly, the nuclease sensitivity of these sites in PSG chromatin is greatly reduced at molting, when *h-fib* is temporarily repressed. The role of such potent regulatory complexes in specifying *h-fib* characteristics of expression remains to be established, but the presence of remote control elements may change our current view of how *h-fib* is activated in the PSG *in vivo*.

2.11.3.2. POU-M1 and the Control of the *ser-1* Promoter

The study of *ser-1* regulation was approached by *in vitro* transcription assays, but in contrast to *h-fib*, marked differences were noted when *ser-1* derived templates were introduced into MSG and PSG cell-free transcription reactions.

The MSG-preferred activation was dependent on the presence of an enhancer located between −239 and −173 (Hui and Suzuki, 1990; Matsuno *et al.*, 1990). Two elements contained in this DNA stretch were found to interact *in vitro* with distinct protein complexes.

The first element contained the target sequence for a POU-type transcription factor. The cloning of POU-M1 was achieved by screening a silk gland cDNA library with a mammalian POU cDNA probe (Fukuta *et al.*, 1993) (**Table 1**). The factor was found to be expressed in the two secretory regions of the silk gland during the fourth molt, but to be absent in the PSG and abundant in the MSG during the following intermolt. These experiments featured POU-M1 as the first isolated regulatory factor of the silk gland with a strict territory-specific incidence at the stage of intense *ser-1* transcription.

The promoter of the POU-M1 gene was also studied by *in vitro* transcription. Devoid of a TATA box, its 5′ DNA was found to carry positively and negatively acting sequences that likely restrict its expression in MSG cells *in vivo*. It also harbors a POU-M1 target sequence, the mutation of which led to an enhanced transcription *in vitro*, suggesting that POU-M1 expression is modulated by a negative autoregulatory control (Xu *et al.*, 1994).

The second sequence element, contained in the −239 and −173 upstream DNA of the *ser-1* gene, was found to be involved in the formation of the so-called SGF1 complex *in vitro*. The DNA-binding component was purified from MSG nuclei and characterized as BmFKH (**Table 1**), the *B. mori* homolog of the Forkhead protein of *Drosophila melanogaster* (Mach *et al.*, 1995). BmFKH is present in both PSG and MSG cells.

Thus, the experiments carried out by Suzuki's group led to the isolation of two factors that displayed distinctive properties. *In vitro*, the *ser-1* promoter studies tended to assign a role of positive regulators to both POU-M1 and BmFKH, and *ser-1* intense transcription was viewed for a while as the result of the combined action of these two factors (Mach *et al.*, 1995). However, as outlined below, this hypothesis is contradicted by the observation that POU-M1 accumulation follows an anteroposterior gradient in the different subparts of the MSG, which is opposite to that of *ser-1* expression. It is, therefore, likely that POU-M1 exerts a negative regulatory function on *ser-1*, and that such an effect has not been noted *in vitro* (Matsunami *et al.*, 1998). Thus, further experiments are needed to

define precisely the relationship between BmFKH and POU-M1 in the process of driving MSG-specific expression of *ser-1*.

2.11.3.3. Regulation of *fhx* Transcription

In vivo experiments were employed to identify the pertinent *cis*-regulatory sequences and their cognate *trans*-binding factors acting on the *fhx* promoter. The use of transgenic *D. melanogaster* as a possible heterologous system was tested first, assuming an evolutionary conservation of the silk gland transcriptional machinery with that of the fruit fly salivary gland (see **Chapter 2.10**). *Drosophila* transgenic lines carrying *fhx* promoter sequences fused to a reporter sequence were made. Remarkably, a transgene containing 1453 bp of *fhx* 5′ flanking DNA was found to be exclusively expressed in the anterior subpart of the larval salivary gland of the fly at all the three larval stages (Bello and Couble, 1990). The absence of expression of the transgene in other tissues strengthened the hypothesis that common-specific factors controlling the spatial and temporal activation of the *fhx* promoter were present in the larval labial gland of the fruit fly and the silkworm. Through sequential deletions, it was demonstrated that the 254 bp stretch of 5′ proximal DNA was necessary and sufficient for conferring the tissue specificity in *D. melanogaster* (Bello *et al.*, 1994). The selective expression of the *fhx-lacZ* transgene in the anterior salivary gland cells and the expression of *fhx* in the PSG cells raised the question of the precise homology between the different subparts of the two organs.

Efforts were made to set up a homologous *in vivo* functional assay in the silk gland cells themselves. This was achieved using a biolistic-aided method by which a silk gland is bombarded with DNA-coated tungsten particles and further grafted into a host larva. This protocol allowed measurements of the activity of transduced DNA constructs in a fully natural physiological environment (Horard *et al.*, 1994). With this assay, it was shown that, as in transgenic *D. melanogaster*, a very short domain of *fhx* upstream sequence is sufficient to drive intense PSG-specific expression of a *fhx-lacZ* fusion gene (Horard *et al.*, 1997). Interestingly, this short domain carries the sequence element TATTTATTTAAC to which BmFKH binds *in vitro*, suggesting that this factor could play a central role in *fhx* expression (Durand *et al.*, 1992; Nony *et al.*, 1995; Julien *et al.*, 2002). *In vivo* chromatin footprinting showed that the target site was occupied in PSG but not in MSG chromatin, and the use of anti-BmFKH antibodies did confirm that the DNA protection was dependent upon the factor (Julien *et al.*, 2002).

Thus, BmFKH (**Table 1**) appeared to be the main regulator of both *fhx* and *ser-1* in PSG and MSG cells, respectively, and this raised questions regarding the nature of the mechanisms that would constrain their spatial expression. It was hypothesized that either the status of the BmFKH factor itself or one of its partners would differ between the two categories of secretory cells, or that the access of BmFKH is limited by independent mechanisms acting on the chromatin organization of PSG or MSG expressed genes, the two propositions being not exclusive of each other.

The characterization of BmFKH in PSG and MSG cells, respectively, using partial proteinase cleavage of the factor complexed to a radioactive probe, and sequencing of the BmFKH mRNA did not reveal any differences for the factor in the two categories of cells (Julien *et al.*, 2002, and unpublished data). Attempts were also made to isolate BmFKH partner proteins by using the yeast two-hybrid technique, but this failed because all the tested BmFKH subpeptides were capable of directly transactivating yeast genes (Julien *et al.*, unpublished data), probably via interactions with general transcription factors including TBP itself, as was demonstrated for a few other factors of the wing-helix Forkhead family (Hellqvist *et al.*, 1998). Thus, the demonstration that BmFKH itself is capable of conferring specificity to *fhx* or *ser-1* promoter activity is still lacking.

The chromatin organization around the *fhx* gene was studied in both PSG and MSG cells taken at the fourth larval molt (when *fhx* is temporarily repressed in PSG cells) and at the fifth intermolt (when *fhx* is actively transcribed in PSG cells). DNAse-I partial digestion revealed the presence of two prominent PSG-specific hypersensitive sites. One of them, centered at −55 and including the BmFKH binding site, disappears when *fhx* is silenced at molting (Julien *et al.*, 2002) (**Figure 3**). The other is located at around +70 and is detected all along the fourth molt and the fifth larval instar. Contrary to that at −55, this site is independent of the transcriptional status of the gene (**Figure 3**). It is relevant to note that these two regions of *fhx* were present in the transgene construct active in *D. melanogaster*.

The significance of the +70 hypersensitive site remains to be established. It is suspected that its PSG-exclusive presence is linked to the mechanisms by which *fhx* chromatin structure is maintained in an active transcriptional configuration in PSG. Indeed, *fhx* activation involves dynamic changes of nucleosome structure during larval development (Julien *et al.*, 2002). While the *fhx* upstream DNA is characterized by a tightly compacted nucleosome

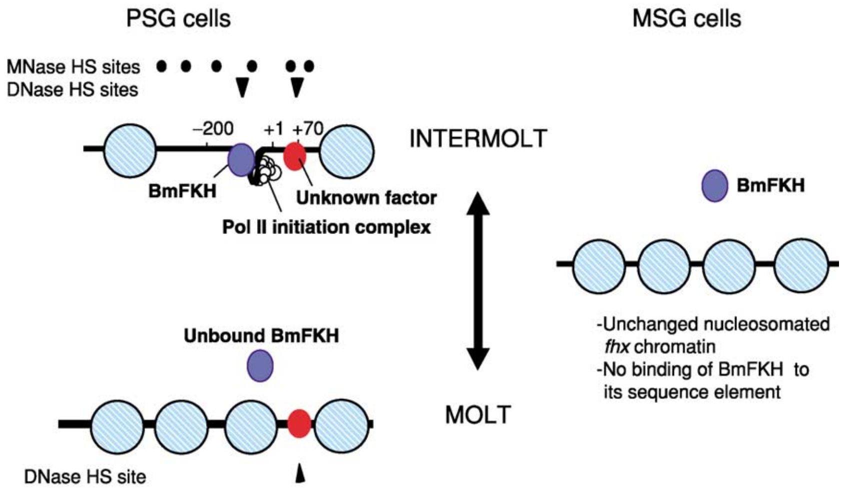

Figure 3 Functioning of the *fhx* promoter. As shown on the left, the *fhx* promoter in PSG cells is alternatively active and inactive during the larval intermolts and molts, respectively. The turning on of the gene is associated with the removal of nucleosomes in the upstream domain of the chromatin, which contains multiple MNase hypersensitive sites and two prominent DNaseI hypersensitives sites, centered at −55 and +70. This active state is also featured by the binding of BmFKH resulting in enhanced transcription. At the onset of molting, BmFKH is excluded from DNA but remains in the nucleus; correlatively, the upstream domain is rapidly nucleosomated and most of the MNase sites and the −55 DNaseI site disappear. The mechanism that prevents BmFKH from stably binding to its target sequence is likely triggered by the signal that promotes larval molts. The hypersensitive site at +70 is a permanent hallmark of *fhx* chromatin in PSG cells, and is thought to channel BmFKH toward its target sequence at the next intermolt. It is suggested that this organization of chromatin governs PSG-specific *fhx* expression. (Data from Horard, B., Julien, E., Nony, P., Garel, A., Couble, P. **1997**. Differential binding of the *Bombyx mori* silk gland specific factor SGFB to its target sequence drives posterior cell restricted expression. *Mol. Cell. Biol. 17*, 1572–1579; and Julien, E., Bordeaux, M.C., Garel, A., Couble, P., **2002**. Fork head alternative binding drives stage-specific expression in the silk gland of *Bombyx mori*. *Insect Biochem. Mol. Biol. 32*, 377–387.)

array in all silk gland cells at molting, the activation of the promoter in the PSG cells during intermolt is accompanied by the loss of nucleosome patterning and an enhancement of its accessibility to micrococcal nuclease (Julien *et al.*, 2002) (**Figure 3**). Thus, changes in the structure of chromatin in the differentiated silk gland cells are probably important for conferring the time and tissue specificity of silk protein gene expression. It is not known how these chromatin changes are orchestrated, but it is tempting to imagine that the establishment of such distinct structures in PSG and MSG cells occurs during the early silk gland organogenesis.

2.11.4. Embryonic Development of the Silk Gland

The embryogenesis of the silkworm lasts 10–12 days at 25 °C. Takami and Kitazawa (1960) recognized 30 distinct morphological stages, to which we refer in the following description of silk gland embryonic development. Pictures of the growing silk gland together with a schematic representation of its morphogenesis are shown in **Figures 4 and 5**, respectively.

The silk glands arise, at stages 18–19, from the recruitment of ectoderm cells in two lateral ventral placodes in the posterior part of the labial segment (parasegment 2) (**Figure 4a and b**). At stage 19, the tip of the presumptive silk gland invaginates from the primordium and becomes visible in the anterior first thoracic segment. As embryogenesis proceeds, the anteroposterior growth of the gland tube follows the lateroventral side of the embryo and, at the time of germ band retraction (stage 20), reaches the mesoderm of the abdominal segment 1. During germ band shortening (stages 21A and 21B), the convex ventral side of the embryo adopts a concave shape (**Figure 4c**). Simultaneously, the silk gland elongates and, at mid-course of abdominal segment 2, its extremity progresses dorsally behind the tracheal pit and grows under the visceral mesoderm toward the dorsal side of the embryo. After reaching a dorsolateral position, the extremity of the gland emerges from the visceral mesoderm and then progresses dorsally toward the posterior direction (**Figure 4c**). During dorsal closure of the embryo (stages 22–23), the future silk gland reaches the most posterior extent of its growth, the tracheal pit of the abdominal segment 6.

During the growth of the silk gland, proliferating cells were identified by 5-bromo-2-deoxyuridine (BrdU) incorporation. Mitoses are detected in only the six to eight subapical cells in contact with the blind-ended tubular extension, from stages 18 to 22, until the organ reaches the abdominal segment 6

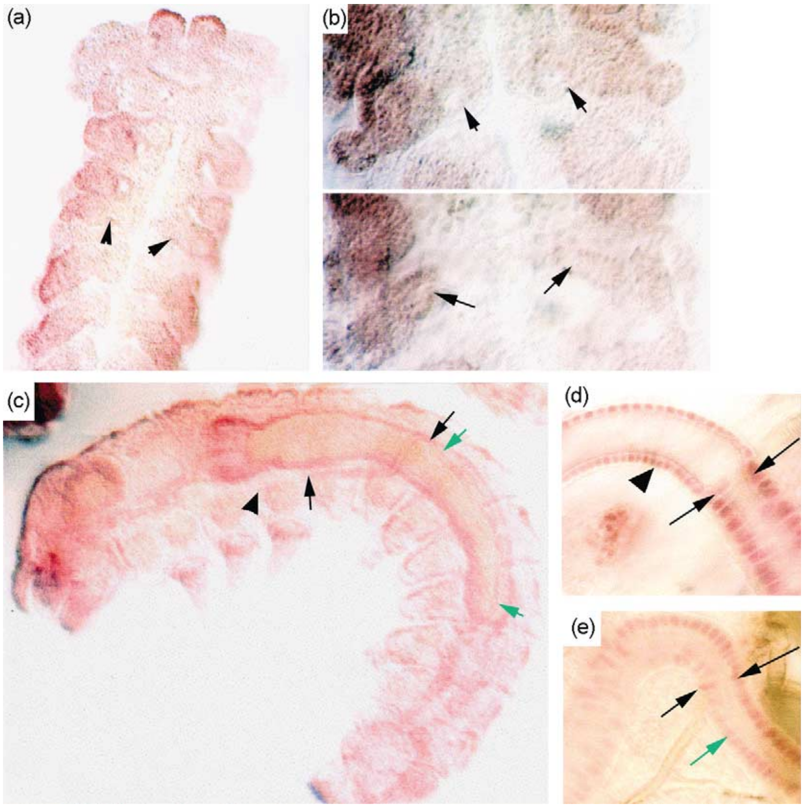

Figure 4 *Bombyx mori* silk gland embryonic development. (a) and (b) are ventral views of embryos at stage 19. In (a) arrows point to the silk gland primordia in the labial segment, enlarged in (b) to show two focal planes of the labial and anterior thoracic segments with the silk glands invaginating from the medial part of the posterior labial segment (arrows). (c) Display of an embryo at stage 24, with the silk gland extending from the labial segment to the dorsolateral abdominal segment 6; the arrowhead points to the future anterior silk gland (ASG); the future middle silk gland (MSG) stretches between the two black arrows and the growing future posterior silk gland (PSG) between the two green arrows. (d–e): Higher magnifications of the junctions between the future ASG and MSG (d) and between the middle and posterior silk glands (e) at stage 24.

(Figure 5). The mitotic activity of these few cells, the mitotic spindles of which run parallel to the long axis of the tube, was also confirmed by observation of Feulgen-stained silk glands. In this regard, silk gland tubulogenesis is comparable to that of the *D. melanogaster* Malpighian tubules (**Chapter 2.8**), which also originate from ectodermic primordia and whose cell proliferation also involves the presence of a single nondividing cell at the distal tip of the growing tubule (Skaer, 1989; Skaer and Martinez-Arias, 1992; see **Chapter 2.8**).

The successive differentiation of the silk gland in three territories by sequential anteroposterior differentiation of the future anterior, median, and posterior cells, respectively, suggests that changes in gene expression occur when and where the transition occurs between the future anterior to median, and median to posterior boundaries. During germ band extension and shortening and during dorsal closure, the interactions between the silk gland tip cells and the other tissues are modified. In particular, the close contacts with visceral mesoderm cells at stage 20 are likely involved in determining the future boundaries between specialized silk gland territories.

Following complete extension of the silk gland at stages 21C–22, a sudden and specific burst of cell divisions takes place in the future MSG at late stage 22, resulting in its extension in the posterior region of the MSG and its forward folding, within PS7 boundaries, as schematized in Figure 5. At this stage, the ASG, MSG, and PSG cells already exhibit distinctive features: the ASG cells are thin and border a large lumen, whereas the MSG cells are large with long nuclei and the PSG cells are more compact with round nuclei (Figure 4d and e). The ASG–MSG and MSG–PSG boundaries are easily visible by microscopic observation.

From late stage 22 onwards, S-phases are not followed by cell divisions, thus fixing the transition from diploidy to polyploidy between stage 23 and late 24. The first burst of DNA endoreplication affects all three territories, but in an asynchronous

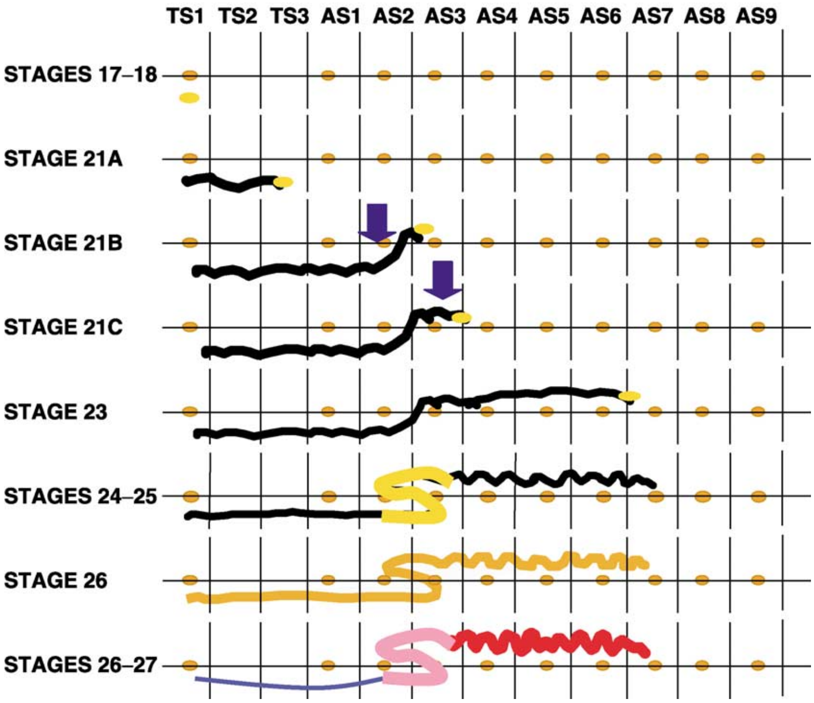

Figure 5 Sequence of morphogenesis of the silk gland during the embryonic development. The chronology of embryogenesis on the left-hand side refers to the 30 morphological stages established by Takami and Kitazawa (1960). At the top of the figure, the anteroposterior axis of the embryo is marked with the limits of the three thoracic (TS1 to TS3) and the nine abdominal (AS1 to AS9) segments. The growing future silk gland is represented as a dark line with a gray patch at the posterior tip symbolizing the six to eight subapical cells of the tube that retain the capacity to divide (see text). At stages 24–25, the cells of the future middle silk gland (MSG) undergo a round of mitoses as symbolized by the yellow line. The initiation of the first round of endomitoses (dark orange) occurs then at stage 26 in the whole silk gland. At late stage 26 (26–27), the silk gland is fully functional and the MSG and PSG cells express the genes that characterize their terminal differentiation, *ser-1* and *ser-2* for the MSG cells (in pink), and *h-fib, l-fib,* and *fhx* for the PSG cells (in red). The two blue arrows signal the stage and place at which the transitions occur between the ASG and the MSG, and between the MSG and the PSG.

manner: MSG cells are the first concerned, then PSG cells and, finally, ASG cells which replicate their chromosomes just before the embryonic molt. At this stage, the number of cells of the silk gland is fixed and is approximately 250, 200, and 500 in the ASG, MSG, and PSG territories, respectively.

2.11.4.1. Comparative Development of the *B. mori* Silk Gland and the *D. melanogaster* Salivary Gland

Genes that likely play a role in silk gland development in *B. mori* have been identified mostly by *in situ* hybridization and histochemistry studies (see also **Chapter 2.10**). Since no mutants are yet available, the involvement of these genes is, most often, inferred from the role of their cognate homologs in *D. melanogaster*, usually with reference to the development of the salivary gland (Andrew *et al.*, 2000; Panzer *et al.*, 1992), the fruit fly homolog of the silk gland.

The silkworm silk gland and the fruit fly salivary gland (see also **Chapter 2.10**) are thought to represent homologous organs, because both originate from lateral ventral placodes of the labial ectoderm. They also differentiate as tubular epithelia with one layer of polyploid secretory cells. Moreover, they exert similar functions of synthesis, secretion and export of a large amount of proteins of repeated structure: the glue proteins encoded by the *sgs* genes in the fruit fly and the silk proteins in the silkworm. The glue proteins link the puparium onto the substratum and silk constitutes the cocoon, a mechanical protection to the pupa. A functional illustration of the homology between the two tissues is the exclusive expression of a *fhx-lacZ* transgene in the salivary gland of transgenic *D. melanogaster*, which strongly suggests that the major elements of the transcription regulating machinery have been conserved through the 250 million years of divergence between the two species (Bello and Couble, 1990). Interestingly, the activity of the *fhx-lacZ* promoter closely mimics that of *fhx* in *B. mori*, by occurring at all larval instars in the fruit fly, in contrast to *sgs* gene expression, which is restricted to

only the last larval instar. The difference probably lies in the hormonal stimulation of transcription of the glue protein encoding genes, which are direct targets of the ecdysone receptor (Lehmann and Korge, 1996). In contrast, *fhx* and the other silk protein-encoding genes are expressed at all larval molts but are not directly controlled by ecdysone.

Despite common traits, the organogenesis of the *D. melanogaster* salivary gland does not follow the same pattern as that of the silk gland. The salivary gland ectodermal placode contains the final number of cells of the tissue prior to invagination, in contrast with the silk gland primordium, which is made of cells that actively divide during subsequent tubulogenesis (Andrew *et al.*, 2000). Moreover, the salivary gland duct, which is made of cuboidal cells, and the secretory part that consists of columnar cells, arise from distinct regions of the placode and are separately organized, whereas in the silk gland, the whole placode gives rise to both the duct and the secretory regions.

2.11.4.2. Genes Involved in Silk Gland and Salivary Gland Development

Efforts have been made to unravel the contribution of various genes at the early phases of silk gland development (see also **Chapter 2.10**). Kokubo *et al.* (1997a) first observed that the mRNA and the protein encoded by the *B. mori* gene *Sex combs reduced* (*BmScr*) accumulate at stage 19 in the labial segment, where ectoderm cells are committed to form the silk gland. They suggested that, similarly to the action of *Scr* in the *D. melanogaster* salivary gland (Andrew *et al.*, 2000), the homeotic *BmSrc* selector gene is a positive regulator of silk gland fates in the silkworm. This hypothesis was supported by the analysis of *Nc* homeotic mutants that lack a portion of the *Antennapedia* gene (*BmAntp*) including the DNA coding for the homeodomain and the C-terminal portion of the protein. In these mutants, *BmScr* expression expands into regions normally controlled by the wild-type *BmAntp* (Nagata *et al.*, 1996). Such ectopic expression of *BmScr* in the thoracic region induces the invagination of additional pairs of silk glands in the three thoracic segments. Thus, it is likely that the cascade of gene control initiated by *Antp* and *Scr* in the *D. melanogaster* salivary gland also occurs in the *B. mori* silk gland.

The embryonic expression of *Bmfkh* (also called *SGF-1* or *SGFB*), the *B. mori* homolog of *forkhead* (*fkh*), was also investigated, since the internalization of the salivary gland primordia and the formation of the secretory tubes are blocked in *D. melanogaster fkh* mutants. In the silkworm, *Bmfkh* mRNA is detected in the invaginating silk gland, and the protein is present at stages 23–25 in the almost fully differentiated secretory cells (MSG and PSG) but not in the ASG ones (Kokubo *et al.*, 1996). *Bmfkh* is, thus, one of the earliest genes expressed in the secretory cells, as is *fkh* in the *D. melanogaster* salivary gland. The functional dependence of *Bmfkh* upon *BmSrc* is suggested by its early expression in the invaginating ectopic silk glands in *Nc* mutants (Kokubo *et al.*, 1997b). However, it is not known whether *BmSrc* activation of *BmFkh* is direct, as is suggested in *D. melanogaster* (Andrew *et al.*, 2000), or indirect.

The protein BmFKH is a wing helix factor that plays crucial roles in the transcriptional regulation of the silk protein encoding genes. As described above (see Sections 2.11.3.2 and 2.11.3.3), BmFKH transactivates the sericin-1 and the fibrohexamerin genes, as shown by *in vitro* (Mach *et al.*, 1995) and *in vivo* (Julien *et al.*, 2002) studies, respectively. Thus, the same factor likely plays a dual role in silk gland development, being first required at the early stages of primordium invagination, tubulogenesis and establishment of secretory cell fates and, after full differentiation is reached, as a key factor in the transcriptional activation of silk protein genes. The role of BmFKH at the early steps of silk gland development has not been studied yet, but may be enlightened by the accurate dissection of the function of *D. melanogaster* Forkhead, which plays three distinct and successive roles in the salivary gland: (1) it prevents apoptosis of salivary gland precursor cells prior to internalization of the placode, (2) it promotes the cell shape changes that trigger the invagination of the future salivary gland, and (3) it directly activates the glue protein encoding genes *sgs-1*, *sgs-3*, and *sgs-4* (Lehmann and Korge, 1996; Mach *et al.*, 1996; Lehmann *et al.*, 1997; Roth *et al.*, 1999; Myat and Andrew, 2000).

Different vertebrate Forkhead-like factors have been shown to exert chromatin-modifying activities, and may be well suited to bind target genes at early development. It is possible that the binding of such factors in precursor cells mediates developmental competence, whereby selected genes are physically discriminated, thus permitting the subsequent steps of differentiation to occur efficiently (review: Zaret, 1999). The presumed conserved dual role of FKH and BmFKH suggests that glue and silk protein genes may gain the competence, at the early stages of development, to become activated after the completion of organogenesis.

Another gene expressed early in *D. melanogaster* salivary gland formation is *trachealess* (*Trh*), which is required for duct cell differentiation (Isaac and

Andrew, 1996). *Trh* encodes a basic loop–helix PAS (Per, ARNT, Sim) protein that functions as a transcription factor (Zelzer *et al*., 1997). *Trh* is initially expressed in the entire salivary gland primordia, but becomes repressed in secretory cells in a *fkh*-dependent manner, suggesting that proper expression of *fkh* and *Trh* is indeed crucial for the distinction between duct and secretory cell fates in the salivary gland (Andrew *et al*., 2000). Interestingly, the study of *B. mori Trh* (*BmTrh*) showed that it is expressed in the labial segment, where the silk gland invaginates. Its expression is maintained in the growing silk gland, but becomes restricted to the future anterior silk gland at stage 23, while *Bmfkh* expression is constrained to the secretory parts (Matsunami *et al*., 1999). Thus, the same restriction of the expression of *forkhead* and *trachealess* in specific territories of the silk and salivary glands emphasizes the conservation of genetic cascades that operate during the development of the two organs.

The expression of the *ser-1* gene has been detected from stage 26 with an increasing anteroposterior gradient pattern in the MSG (Matsunami *et al*., 1998). A *ser-1* transcriptional regulator known as SGF-3/POU-M1 was detected from stage 20 in the whole silk gland. Interestingly, its expression rapidly vanishes in PSG and, from stage 26 onwards, it is detected only in the ASG and MSG cells. In MSG cells, SGF-3/POU-M1 exhibits a decreasing anteroposterior gradient pattern suggesting that it acts as a negative regulator of *ser-1* transcription (Matsunami *et al*., 1998). It is present in many organs of the embryo and its contribution to the early differentiation of the silk gland remains to be deciphered.

Finally, a few other genes have been isolated from the silkworm, whose expression also occurs at the early stages of silk gland organogenesis and in specific subregions of the organ. The study of the *wnt-1* (*wingless*) and *Ci* (*Cubitus interruptus*) homologs revealed that these are coexpressed in the anterior portion of the MSG at late embryogenesis and throughout larval development (Dhawan and Gopinathan, 2002). Interestingly, the turning on of these genes in the anterior portion of the MSG is functionally relevant, because this region is occupied by the *ser-2* expressing cells. However, the mechanisms that spatially constrain *wnt-1* and *Ci* expressions and the relationship between activities of these two factors and *ser-2* transcription regulation are not known. Part of the answer may lie in the exclusive expression of *engrailed*, a potent suppressor of *Ci*, which is precisely expressed in the middle and posterior portion of the MSG (K.P. Gopinathan, personal communication).

2.11.5. Conclusions and Future Prospects

The long standing study of *B. mori* silk gland embryonic development and the mode of gene regulation in the MSG and PSG cells has provided a wealth of information. Two factors, BmFKH and POU-M1, have been identified and isolated, which participate in the region-specific transcription of silk protein encoding genes. These two factors were also found to be expressed at early stages of silk gland morphogenesis, before MSG and PSG cells differentiate into sericin- and fibroin-secreting cells. This raises the question of the dual roles played by these factors before and after cell differentiation during silk gland development. Such a plural function has been assigned to HNF3, a factor belonging to the Forkhead family, and to a GATA protein, for the formation of tissues from the gut endoderm (Zaret, 1999). Their role is to promote a developmental competence to target genes, such as the albumin gene in the hepatic primordium, by inducing a specific, chromatin structure that discriminates them from the nonexpressed genes.

Most of the hypotheses on how transcription is controlled in the differentiated silk gland stipulate the existence of MSG- or PSG-specific factors. However, it should be noted that, to date, this simple view has not been demonstrated, either for activators or for repressors. At the same time, the study of *fhx* regulation has revealed that PSG-specific expression depends on a PSG-specific chromatin organization of the gene. This strongly suggests that the differential accessibility of the *trans*-acting factors to their target sequences may play the central role in building up the silk gland phenotype.

Complete understanding of silk protein gene regulation will most probably be brought about by investigating the *in vivo* mechanisms that allow the embryonic silk gland cells to become committed to MSG or PSG cell fates. It can be hypothesized that the acquisition of a competence to become a MSG or a PSG cell rests upon the potentiation of the different silk protein-encoding genes by a combination of factors that are present in the immature MSG or PSG cells. Analysis of the embryonic development of the silk gland showed that BmFKH and POU-M1 are early factors that discriminate the future ASG portion from the future MSG and PSG secretory parts and the PSG from the MSG parts, respectively. Owing to its key role in activating *ser-1* and *fhx*, it can be proposed that BmFKH may be a master element in the process of potentiating silk protein encoding genes, which all have a BmFKH binding element in their immediate upstream DNA.

BmFKH alone, however, cannot determine the fate of MSG and PSG cells and likely interacts with other factors that have yet to be identified. POU-M1 may be viewed as playing such a role.

The study of the role of chromatin organization of silk protein genes will benefit from the powerful *in vivo* experimentation using transgenic silkworms (Tamura *et al*., 2000). Indeed, it is now possible to correlate the acquisition of proper chromatin structure and transcriptional competence with the presence of pertinent *cis*-acting sequences carried by modified transgenes.

The differentiation of the three subparts of the embryonic silk gland probably involves unknown genes that do not directly regulate silk protein gene expression. Their isolation and characterization will be facilitated by the sequencing of the silkworm genome and by new high-throughput procedures of transcriptome and proteome analyses. These post-genomic approaches will provide new data on the contribution of specific genes to the determination and differentiation of the silk gland.

Which of the developmental mechanisms are conserved between or are unique in the *B. mori* silk gland and the *D. melanogaster* salivary gland? Although silkworm mutants for all the genes under study are not available, the creation of phenocopies by RNA interference is feasible, as is the testing of the capacity of *B. mori* genes to correct defects in relevant *D. melanogaster* mutants. These approaches will open a new era of research, aimed at the understanding of the integration of functions in secretory cells, for which the silk gland remains one of the most remarkable models.
